 J. Norberto Pires, Coimbra, Portugal
 Rainer Bischoff, Augsburg, Germany

55 Space Robotics

Kazuya Yoshida, Sendai, Japan
 Brian Wilcox, Pasadena, USA
 Gerd Hirzinger, Wessling, Germany
 Roberto Lampariello, Wessling, Germany

56 Robotics in Agriculture and Forestry

Marcel Bergerman, Pittsburgh, USA
 John Billingsley, Toowoomba, Australia
 John Reid, Moline, USA
 Eldert van Henten, Wageningen, The Netherlands

57 Robotics in Construction

Kamel S. Saidi, Gaithersburg, USA
 Thomas Bock, Munich, Germany
 Christos Georgoulas, Munich, Germany

58 Robotics in Hazardous Applications

James Trevelyan, Crawley, Australia
 William R. Hamel, Knoxville, USA
 Sung-Chul Kang, Seoul, Korea

59 Robotics in Mining

Joshua A. Marshall, Kingston, Canada
 Adrian Bonchis, Pullenvale, Australia
 Eduardo Nebot, Sydney, Australia
 Steven Scheduling, Sydney, Australia

60 Disaster Robotics

Robin R. Murphy, College Station, USA
 Satoshi Tadokoro, Sendai, Japan
 Alexander Kleiner, Linköping, Sweden

61 Robot Surveillance and Security

Wendell H. Chun, Denver, USA
 Nikolaos Papanikolopoulos, Minneapolis, USA

62 Intelligent Vehicles

Alberto Broggi, Parma, Italy
 Alex Zelinsky, Canberra, Australia
 Ümit Özgüner, Columbus, USA
 Christian Laugier, Saint Ismier, France

63 Medical Robotics and Computer-Integrated Surgery

Russell H. Taylor, Baltimore, USA
 Arianna Menciassi, Pisa, Italy
 Gabor Fichtinger, Kingston, Canada
 Paolo Fiorini, Verona, Italy
 Paolo Dario, Pisa, Italy

64 Rehabilitation and Health Care Robotics

H.F. Machiel Van der Loos, Vancouver, Canada
 David J. Reinkensmeyer, Irvine, USA
 Eugenio Guglielmelli, Rome, Italy

65 Domestic Robotics

Erwin Prassler, Sankt Augustin, Germany
 Mario E. Munich, Pasadena, USA
 Paolo Pirjanian, Bedford, USA
 Kazuhiro Kosuge, Sendai, Japan

66 Robotics Competitions and Challenges

Daniele Nardi, Rome, Italy
 Jonathan Roberts, Brisbane, Australia
 Manuela Veloso, Pittsburgh, USA
 Luke Fletcher, Brisbane, Australia

Part F, Robots at Work, covers the advances in technology that are concerned with the growing area of robot applications, ranging from factory robotics, through a diverse array of industry applications such as mining, agriculture, construction to health care and domestic robotics. The future vision for robotics is for the pervasive application of robots. The robots of the future will perform all the dangerous, dirty, and dreary (DDD) tasks. Joe Engelberger, the pioneer of the robotics industry, wrote in his 1989 book *Robotics in Service* that the inspiration to write the book came as a reaction to a forecast study of robot applications, which predicted that in 1995 applications of robotics outside factories (the traditional domain of industrial robots) would account for less than 1% of total sales. Engelberger believed that this forecast was wrong, and he instead predicted that the non-industrial class of robot applications would become the largest class of robot applications. Engelberger's prediction has yet to come to pass. However, he did correctly foresee the growth in non-traditional applications of robots. Previous parts of this Handbook show the great strides that robotics technology has made in the past 50 years. The technology has reached a level of maturity such that robots are now marching from the factories into field and service applications.

The topics in Part F cover the essentials of what is required to create robots that can operate in all environments and perform meaningful work. Part F describes fit-for-purpose robots and includes hardware design, control (of locomotion, manipulation, and interaction), perception, and user interfaces. The economic/social drivers for the particular applications are also discussed. Part F builds on all of the previous parts of the Handbook. Robotics Foundations (Part A) and Design (Part B) are essential for providing the basic mechanisms and control structures for any robot that is targeted for applications work. Sensing and Perception (Part C) and Manipulation and Interfaces (Part D) are critical capabilities for robots that need to interact with changing environments and perform manipulation tasks under human supervision. To fully utilize the potential of a working robot requires mobility and the ability to cooperate with other robotics, the basic technologies described in Moving in the Environment (Part E) are essential.

Chapter 54, Industrial Robotics, gives a history and description of typical industrial robot applications. Most robots today can trace their origin to early industrial robot designs. All the important foundations for robot control were initially developed with industrial applications in mind. The chapter describes how robot with different mechanisms are designed to fit different applications.

Chapter 55, Space Robots and Systems, deals with robotics technology for space applications. It covers two classes of robotics: orbital systems and operation of planetary surfaces. Any unmanned spacecraft is a robotic spacecraft. However, space robots are more capable devices that can facilitate manipulation, assembly, assisting astronauts, and extending exploration to remote planets as surrogates for human explorers. This chapter covers the key issues in space robots and systems: manipulation, mobility, sensing and perception, tele-operation and autonomy, and dealing with extreme environments. A historical overview and a review of the most recent technical advances for space robots is provided. An extensive description of the mathematics for the control of robotic devices in microgravity environments is also provided.

Chapter 56, Robotics in Agriculture and Forestry, describes how robotics has made an impact in the agricultural and forestry industries. Agriculture is an industry that is driven by productivity. Growing human population drives ever-increasing demands for greater food production. Robotics is a productivity technology that can be game changer in agriculture. The chapter focuses on case studies where robotics has made a marked difference to agriculture and forestry. The case studies cover the use of robotics in field crops, weeding, seeding, irrigation, orchard crops – fruit and vegetables, forestry, and livestock applications – breeding, harvesting, slaughter and processing. The case studies follow the progression of robotics technology from sensing through mobility to manipulation. The chapter emphasizes the agricultural field as a fruitful source for robotics applications, that are sufficiently demanding to require the development of new techniques, methods and technologies.

Chapter 57, Robotics in Construction, describes the construction automation concepts that have been developed and presents examples of construction robots that are in use and are in various stages of development. The chapter gives an overview of the construction industry and discusses the concept of automation versus robotics. The chapter discusses robotics in applications that are on construction sites. The chapter deals with the growing number robotics and automation application of offsite construction tasks such as prefabrication. Unsolved technical challenges including interoperability, connection systems, tolerances, power, and communications are discussed.

Chapter 58, Robotics in Hazardous Applications, discusses robot technologies for dealing with difficult and dangerous environments. The technology solutions that are adopted depend on the nature and magnitude of

the hazards. When the magnitudes of hazards reach the point that human exposure represents a direct threat to life or has long-term health consequences, e.g., nuclear radiation, some form of remote operation must be used. This chapter describes robotics technologies for dealing with eradicating landmines, and hazardous materials handling, such as explosives disposal, and handling of dangerous biological and nuclear material. Enabling technologies to support demining and hazardous material handling are discussed, including mobile platforms, manipulator design, teleoperation and control, and the supply of energy and communication signals through reliable and robust tethers. The chapter ends with a discussion of the advances that are required to progress the field. Progress is needed in mechatronics design, sensing, machine intelligence, and fully understanding the application and its associated economic factors.

Chapter 59, Mining Robotics, discusses the application of robotics to the mining industry. Mining remains physically demanding and hazardous work. The scope for the application of robotics is great since mining requires the handling of enormous quantities of material in a cost-effective and safe manner. High operational costs, the need for greater productivity, and improved health and safety outcomes are powerful drivers for robotics. Robotics and automation is providing the next step change in productivity and safety. This chapter reviews the modern mining practice and the technology drivers. It describes the enabling robot technologies associated with surface mining and underground mining. The chapter covers the technologies associated with digging, drilling, explosives handling, haulage, truck fleet management, autonomous mapping of mines and robotic rescue for recover in mining accidents. The chapter considers the challenges associated with mining in extreme environments such as undersea extraction of resources and the long-term possibilities of interplanetary exploration and mining.

Chapter 60, Disaster Robotics, describes the state of the art of an emerging applications field. In recent times robots have served as extensions of responders to a disaster, providing real-time video and other sensory data about the situation. The technology is still emerging and is beginning to be adopted by the international emergency response community. Robots are being used by fire departments and for bomb disposal. This chapter describes the basic nature of disasters, the impact on robot design, the types of robots actually used in disasters such as the Fukushima Nuclear disaster, promising designs, future concepts and benchmarks for evaluation of disaster robotics. The chapter discusses the fundamental challenges facing disaster robotics, including

the key challenge of evolution from a concept to the adoption as a solution technology.

Chapter 61, Robot Surveillance and Security introduces surveillance and security robots for military and civil applications. The chapter describes the applications environment that covers ground, aerial and maritime domains for a wide range of surveillance and security robots. A systems overview is provided of the mobility component, sensor payload, communication system, and operator control interface, together with a description of the enabling technologies. The chapter concludes with a review of current research topics and discusses the future direction of robotic surveillance and security.

Chapter 62, Intelligent Vehicles, describes the emerging robotics application field of intelligent vehicles: motor vehicles that have autonomous functions and capabilities. The chapter describes why the development of intelligent vehicles is important and gives a brief history of the field and the potential benefits of the technology. It describes the enabling technologies for intelligent vehicles to sense vehicle, environment, and driver state, work with digital maps and satellite navigation, and communicating with intelligent transportation infrastructure. The chapter describes the challenges and solutions associated with road scene understanding. Advanced driver assistance systems which use robotics technologies to create new safety and convenience systems for motor vehicles, such as collision avoidance, lane keeping, parking assistance, as well as driver monitoring to mitigate against driver fatigue, inattention, and impairment are described.

Chapter 63, Medical Robotics and Computer-Integrated Surgery describes the development of medical robotics. In the last 20 years starting with brain surgery, orthopaedics, endoscopic surgery, and microsurgery, the field has expanded to include commercially marketed, clinically deployed systems and an active research community. This chapter provides a historical review of the field and discusses the major thrusts using examples from current and past research. Medical robots are described within the context of larger computer-integrated systems including presurgical planning, intraoperative execution, and post-operative assessment and follow-up. The basic concepts of computer-integrated surgery including the critical factors affecting the deployment and acceptance of medical robots are described. An overview of medical robot systems is provided, including remote telesurgery and robotic surgical simulators. The chapter concludes with a discussion on future research directions.

Chapter 64, Rehabilitation and Health Care Robotics, describes robotic systems that assist persons who have a disability or provide rehabilitation therapy for persons. The chapter provides a historical review of the field. Physical therapy and training robots as well as robotic aids for people with disabilities are described. Advances in smart prostheses and orthoses for rehabilitation robotics are also described. An overview of work in diagnosis and monitoring for rehabilitation is provided. The chapter provides a solid understanding of the future challenges for rehabilitation and health care robotics.

Chapter 65, Domestic Robots, describes the technology that everyone would one day like in their home, which will vacuum the house, clean the kitchen, load the dishwasher, or polish the shoes. In spite of hundreds of millions of potential users surprisingly not many domestic robots exist, with one notable exception – the Roomba! This chapter examines what have been the success factors for commercializing domestic robots using cleaning robots as a representative example. The chapter reviews domestic floor cleaning robots, robotic pool cleaners, window cleaning robots, and robotic lawn mowing. The chapter also examines

smart appliances such as sports robotics, and telepresence robots. A description of research projects for smart environments and smart homes is presented. The chapter describes the important underpinning technologies for domestic robots covering sensing, obstacle avoidance, localization, mapping and coverage.

Chapter 66, Robotics Competitions and Challenges, explores the use of competitions to accelerate robotics research and to promote education. Robot competitions have been shown to drive innovation in the robotics field. The chapter covers the two broad types of robot competition: human-inspired competitions and task based challenges. Human-inspired robot competitions, which are mostly sports contests, develop platforms that support problem solving. Task based challenges attract participants by presenting a tough new challenge for robotics technology. Three case studies of robot competitions are presented Robot Soccer, the Unmanned Aerial Vehicles (UAV) Challenge and the DARPA (Defense Advanced Research Projects Agency) Grand Challenges. The case studies describe the organizational challenges for participants, the benefits and limitations of competitions and what it takes to have a *good* robot competition.

54. Industrial Robotics

Martin Hägele, Klas Nilsson, J. Norberto Pires, Rainer Bischoff

Much of the technology that makes robots reliable, human friendly, and adaptable for numerous applications has emerged from manufacturers of industrial robots. With an estimated installation base in 2014 of about 1.5 million units, some 171 000 new installations in that year and an annual turnover of the robotics industry estimated to be US\$ 32 billion, industrial robots are by far the largest commercial application of robotics technology today.

The foundations for robot motion planning and control were initially developed with industrial applications in mind. These applications deserve special attention in order to understand the origin of robotics science and to appreciate the many unsolved problems that still prevent the wider use of robots in today's agile manufacturing environments. In this chapter, we present a brief history and descriptions of typical industrial robotics applications and at the same time we address current critical state-of-the-art technological developments. We show how robots with different mechanisms fit different applications and how applications are further enabled by latest technologies, often adopted from technological fields outside manufacturing automation.

We will first present a brief historical introduction to industrial robotics with a selection of contemporary application examples which at the same time refer to a critical key technology. Then, the basic principles that are used in industrial robotics and a review of programming methods

will be outlined. We will also introduce the topic of system integration particularly from a data integration point of view. The chapter will be closed with an outlook based on a presentation of some unsolved problems that currently inhibit wider use of industrial robots.

54.1 Industrial Robotics: The Main Driver for Robotics Research and Application

Even though robots are considered a cornerstone of today's competitive manufacturing particularly in automobile and related component assembly, there are still challenges to solve for manufacturing to efficiently respond to changing consumer behavior and global shifts in competitiveness. Furthermore, high-growth industries (in electronics, food, logistics, and life-sciences) and emerging manufacturing processes (gluing, coating, laser-based processes, precision assembly, fiber material processing) as well as fulfilling sustainability regulations will increasingly depend on advanced robot technology [54.1]. Additionally, the range of feasible applications could significantly increase if robots were easier to install, to integrate with other manufacturing processes, and to program, particularly with adaptive sensing and automatic error recovery. Further challenges result from the integration of various types of controls (programmable logic controller (PLC), computer numerical control (CNC) sensors) with the robot controller, from close human-robot collaboration and fenceless production with both lightweight and heavy duty robots, and from an increasing need to save energy.

Design and production of industrial robots on the one hand, and the planning, integration, and operation of robot work cells on the other hand are largely independent engineering tasks. In order to be produced in sufficiently large quantities, a robot design should meet the requirements for the widest set of potential applications. As this is difficult to achieve in practice, various classes of robot designs regarding payload capacity, number of robot axes, and workspace volume have emerged for application categories such as assembly, palletizing, painting, welding, machining, and general handling tasks.

Generally, a robot workcell consists of one or more robots with controllers and so-called robot peripherals, e.g., grippers or tools, safety devices, sensors, and material transfer components for moving and presenting parts. Typically, the cost of a complete robot workcell is four to five times the cost of the robots alone; however, efforts are underway to drastically reduce these costs through use of increased robot functionality and artificial intelligence [54.2]. A robot workcell is usually the result of customized planning, integration, programming, and configuration, requiring significant engineering expertise. Standardized engineering methods, tools, and best-practice examples for specifying and designing robot workcells have become available to provide predictable performance and to secure investments [54.3].

Today's industrial robots are mainly rooted in the requirements of capital-intensive large-volume manufacturing, typically defined by the automotive, electronics, and electrical goods industries which make up 80% of all robot installations. Future industrial robots will not be a mere extrapolation of today's designs, but will rather follow new design principles addressing a much wider range of application areas and industries. At the same time, new technologies, particularly from the information technology (IT) or the consumer domain will have an increasing impact on the design, performance, use and cost of future industrial robots.

International and national standards now help to quantify robot performance and define safety precautions, geometry, and media interfaces [54.4]. Most robots operate behind secure barriers to keep people at a safe distance. Recently, improved safety standards have allowed direct human-robot collaboration, permitting robots and human factory workers to share the same workspace [54.5, 6].

54.2 A Short History of Industrial Robots

The invention of the industrial robot dates back to 1954 when inventor George Devol filed a patent on a *programmed article transfer* (Fig. 54.1). After teaming up with young engineer and entrepreneur Joseph Engelberger, the first robot company, Unimation, was founded. It put the first robot into service at a General Motors plant in 1961 for extracting parts from a die-casting machine. Most of the hydraulically actuated Unimates were sold through the following years for workpiece handling and for spot-welding of car

bodies [54.7]. Soon, many other companies started to develop and manufacture industrial robots in many industrial nations; an innovation-driven industry was born [54.8]. The first International Symposium on Industrial Robotics (now ISR) took place in Chicago in 1970 and proved that robotics had become the field of activity of a vibrant research community.

The breakthrough Stanford Arm was designed as a research prototype in 1969 by Victor Scheinman (Chap. 4). The six-degree-of-freedom (6-DOF) all-

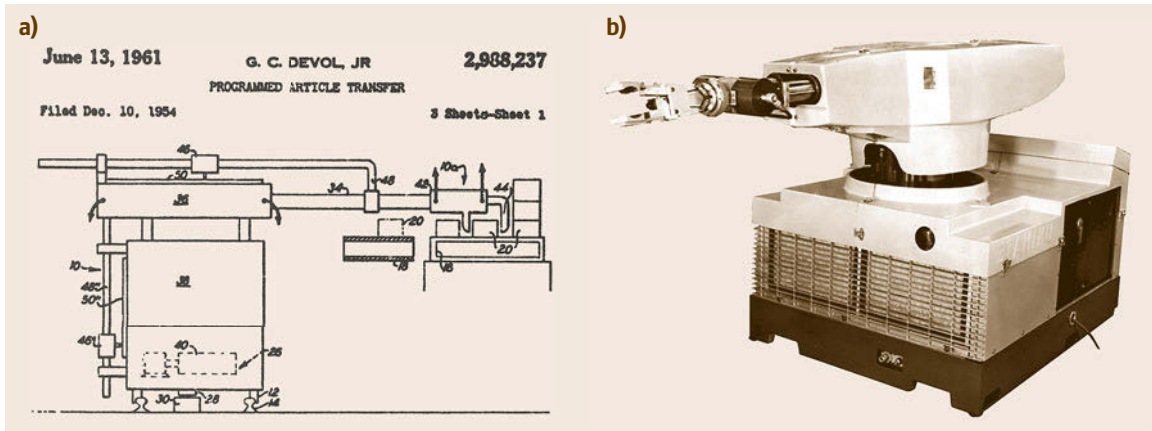

Fig.54.1a,b The invention of the industrial robot. **(a)** This patent was the start of a joint effort between G. Devol and J. Engelberger to form the first robot company, Unimation, a fusion of the terms *universal* and *automation*. The company was acquired by Westinghouse in the late 1980s and subsequently taken up by Stäubli in 1988. **(b)** The first Unimation performed a rather simple handling task in 1961 at a General Motors plant; other car manufacturers followed (courtesy of Smithsonian Institution Archives, Washington DC)

Fig.54.2a,b The all-electric **(a)** IRB-6 and **(b)** a SCARA-type kinematic. **(a)** First introduced in 1973, the IRB-6 has been a breakthrough development as it was the first serially produced robot product, which combined all-electric-drives technology and a microcomputer for motion control and programming. The robot proved very robust, and life-times of more than 25 years in harsh productions were reported (courtesy of ABB Automation). **(b)** The selective compliance assembly robot arm (SCARA) is particularly suited for assembly tasks as it combines rigidity in the vertical axis and compliance in the horizontal axis. In 1978, the first Hirata AR-300 was put together. Depicted is the successor design, the AR-i350 (courtesy of HIRATA Robotics, Mainz)

Fig. 54.3a,b The KUKA IR 601/60 (a) and the Unimation PUMA (programmable universal machine for assembly) 560 (b). (a) In 1978, the novel 6 DOF KUKA robot featured a parallel linkage for its second and third axes. At almost two tons of own weight, it could handle payloads of some 60 kg at maximum operating speed. The robot quickly became a workhorse for the automotive industry. (b) The six axis PUMA was inspired by the dexterity of a human arm. After its launch in 1979 by Unimation, it became one of the most popular arms and was used, due to its versatility and ease of use, as a reference in robotics research for many years

electric manipulator was controlled by a state-of-the-art computer of the time, a DEC PDP-6. The nonanthropomorphic kinematic configuration with one prismatic and five rotational joints was configured such that the equations for solving the robot kinematics were simple enough to speed up computations. Drives consisted of direct-current (DC) electric motors, harmonic drive and spur gear reducers, potentiometers and tachometers for position and velocity feedback [54.9]. Subsequent robot designs were strongly influenced by Scheinman's concepts (Figs. 54.2 and 54.3).

In 1973, the company ASEA (now ABB) introduced the first microcomputer-controlled all-electric industrial robot, the IRB-6, which allowed continuous path motion (CP), a precondition for many applications such as arc welding or material removal (Fig. 54.2). In the 1970s, intense diffusion of robots into car manufacturing set in mostly for (spot-)welding and handling applications (Fig. 54.3) [54.10].

In 1978, the selective compliance assembly robot arm (SCARA) was invented by Makino of Yamanashi University, Japan [54.11]. The ground-breaking four-axis low-cost design was perfectly suited for small parts assembly as the kinematic configuration allows fast and compliant arm motion (Fig. 54.4). Flexible assembly systems based on the SCARA robot in conjunction with compatible product designs (DFA) have contributed significantly to creating a boom in high-volume electronics production and consumer products [54.12]. Further optimization of robot dynamics and accuracy led to the first direct-drive SCARA robot, the AdeptOne in 1984 [54.13].

Requirements regarding a robot's speed, accuracy and weight have led to novel kinematic and transmission designs. An approach toward lightweight and stiff structures has been pursued since the 1980s by developing parallel kinematic machines (PKM) which connect the machine's basis with its end-effector by three to six parallel struts, see also Fig. 54.5. These so-called parallel robots (Chap. 4 and 18) are particularly suited to achieve short cycle times (e.g., for picking), precision (e.g., for material removal), or handling high workloads (Fig. 54.5) and have found their niches in advanced manufacturing [54.14]. However, workspace volumes tend to be significantly smaller than those of serial or open kinematic chain robots which are comparable in size.

Efforts of reducing mass and inertia of serial robot structures have been a primary research target, where the human arm with a weight-to-load ratio better than 1 : 1 was considered the ultimate benchmark. In 2006, robot manufacturer KUKA introduced their LBR lightweight prototype robot, a compact 7-DOF robot arm with advanced torque-control capabilities which has recently been introduced in high-performance industrial applications [54.15]. An obvious next step in approaching human dexterity is the recent introduction of two-armed robot designs with some recent developments being depicted in Fig. 54.7 [54.16]. In conjunction with a robot's capability to support safe human-robot collaboration, new manufacturing concepts can be implemented which expand capabilities, productivity, and ergonomic quality to manual workplaces [54.17].

Fig. 54.5a–c Parallel robots are slowly diffusing into various fields of industrial application: (a) the Neos Tricept 600, (b) Fanuc F-200iB. (c) Adept Quattro. (a) In 1992, Neos Robotics represented with their Tricept robot range a concept to combine the stiffness of machine tools with the dexterity of a robot for heavy-duty applications such as in friction stir welding (FSW) or machining of aluminum for the aircraft industry. (b) The Fanuc F-200iB introduced in 2002 is a 6-DOF parallel robot particularly designed for welding gun handling, deflashing, or for assembly tasks (100 kg payload, ± 0.1 mm accuracy) in automotive assembly processes; (c) the Adept Quattro (introduced in 2007, following the ABB FlexPicker in 1998) is suited for high-speed applications in packaging, manufacturing, assembly, and material handling. The quad dual-link arm design forms an over-determined kinematic linkage, which in the wrist is converted to the forth axis of end-effector rotation by means of an internal transmission in the wrist

In parallel to industrial robots, automated guided vehicles (AGV) have emerged. These mobile robots are used for moving workpieces or loading equipment following a predetermined or virtual path in industrial environments. Within the concept of automated flexible manufacturing systems (FMS) AGVs have become an important part of their routing flexibility. Initially, AGVs relied on prepared floors such

as embedded wires, magnets, or other tags for motion guidance. Meanwhile, freely navigating AGVs along virtual trajectories are entering large-scale manufacturing and logistics. Usually, their navigation is based on laser scanners that provide an accurate two- or even three-dimensional map of the actual environment for self-localization and obstacle avoidance. Early on, combinations of AGVs and robot arms were sug-

Fig.54.6a,b Mobile robots were introduced in the early 1980s for increased flexibility and reliability in factory logistics. (a) The MORO (1984) developed at Fraunhofer IPA was one of the first prototypes to combine a robot arm on a wire-bound mobile platform which follows a wire buried in the floor. gested to automatically load and unload machine tools (Fig. 54.6). Safety and power supply have been an obstacle to these system's diffusion in industrial practice. Currently, first solutions for mobile manipulation appear [54.18].

The ability to use human and robot workers either interchangeably or in workspace sharing/collaboration scenarios in human workplaces motivated the design of anthropomorphic dual-arm robots (Fig. 54.7). Even though industrial acceptance initially has been low, advances in programming comfort, securing safe human–robot coexistence/collaboration and system cost have led to significant interest in using dual arms in agile manufacturing concepts, particularly in assembly and handling applications [54.19]. The dual-arm sys-

tems suggest a new way of using powerful and lean type of robot which is easy to install by the manufacturing end-user with little adaptation of manual workplaces.

Today, industrial robotics is seen as a central pillar to future manufacturing competitiveness and economic growth:

- The International Federation of Robotics (IFR) estimates that between 2000 and 2008 the robotics industry had created 8–10 million highly qualified jobs, either directly or indirectly. The prediction is that between 2012–2020 another 4 million jobs will be created in the *robot ecosystem* [54.20]. The extent of job creation by robotics has been dis-

cussed controversially. It is undisputed, however, that a wider use of robots in manufacturing is able to significantly strengthen a competitive position of a company or an industrial sector [54.21]. Economically, manufacturing productivity gains are particularly effective for economic growth. There is no sustainable product innovation without manufacturing competence which includes knowledge and practice of planning, designing, and operating advanced robotic systems [54.22] (Fig. 54.8).

- The average price for a robot in 2014 was in the order of US\$ 46 800, which is about one-third of its equivalent price in 1990. At the same time, robot performance parameters such as speed, load capacity, and mean time between failures (MTBF) have dramatically improved. This means that automation has become more affordable, providing a faster return on investment [54.1].
- Traditionally, robot automation has not played a significant role in the implementation of lean manufacturing strategies. However, efforts are underway to introduce industrial robots to lean, agile manufacturing. Characteristics are robot solutions that can be flexibly added to manufacturing systems *on demand*, that are significantly less expensive on a life-cycle-costing (LCC) basis than today's systems due to reduced peripherals and systems integration (*system out of the box*) [54.23]. With robots becoming commodities in manufacturing they might be used as intuitively and naturally as a handheld power tool today. This would imply intuitive and safe human–robot collaboration and

versatility due to advanced sensing, control, and embedding the robot set-up and operation in an IT infrastructure.

- Factories of the future will represent a network of self-organizing cyber physical systems (CPS). As part of this industrial internet CPSs embed computation, networking, and physical processes and can either represent manufacturing equipment such as machine tools, fixtures, trays, conveyors, tools, etc. or the workpiece which controls and memorizes its production. Robots are considered the centerpiece of future smart factories which combine manufacturing agility, profitability, human ergonomics, and minimized resource consumption [54.24].
- Robots in assembly have not reached their predicted installation potential mainly due to cheap labor cost and the lean assembly work systems which support highest flexibility and productivity at minimal waste. A reason is partly seen in the slow advances in dexterous manipulation for assembly tasks with industrial robustness. Here, torque-controlled lightweight robots [54.25] and two-armed robot systems have been proposed to imitate human ergonomics and task execution [54.26].
- New financing models such as leasing, *pay by service* will allow end-users to use robots on demand or to have manufacturing service providers to operate manufacturing lines on a *pay-on-production* basis [54.27].

Figure 54.8 depicts some key figures on the recent extent of industrial robot diffusion into manufacturing.

54.3 Industrial Robot Kinematics

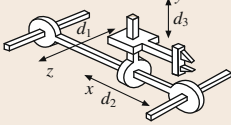

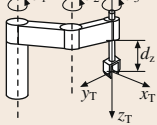

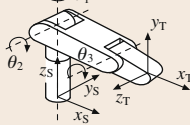

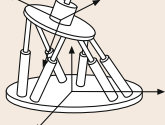

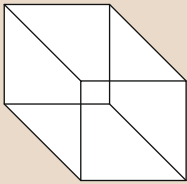

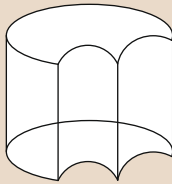

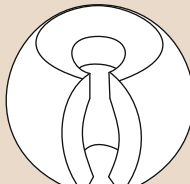

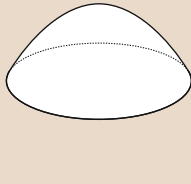

By definition, an industrial robot is an automatically controlled, reprogrammable, multipurpose manipulator, programmable in three or more axes, which can be either fixed in place or mobile for use in industrial automation applications [54.28]. Robots can be categorized according to their number of independent kinematic axes, and their mechanical structure which affect most of the robots' kinematic properties, the computation methods used to determine joint motions, and the form and size of the robot workspace. Robot mechanical structures are composed of links that are rigid bodies connecting neighboring (prismatic, rotary, cylindrical or spherical) joints. The diagrams in Table 54.1 show several common types of robot mechanical structures. Of course, the workspace of industrial robots can be significantly expanded by placing the robot arm on an additional linear axis, sometimes reaching a length of more than 50 m, or even on mobile platforms. Fur-

thermore, robot mechanical structures can be composed by joint modules which are connected by links to form task-specific designs.

With advances in the state of the art in motion control and computer hardware processing capabilities, computation is much less a constraint on mechanism choice than it was for early robot designers. The choice of mechanical structure of the robot depends mostly on fundamental mechanical requirements such as payload and workspace size. Considering a given level of cost, there is usually a trade-off between workspace size and stiffness. To enable the robot to reach inside or around obstacles it is clearly advantageous to use an articulated mechanical design.

Considering also the stiffness and accuracy (in a practical sense considering what is reasonable to build), the picture is more complex. Each of the first three types in Table 54.1 we refer to as serial kinematic

Table 54.1 Main categories of mechanical structures of industrial robots: Gantry is what a Cartesian coordinate robot is typically called with three prismatic joints, whose axes are coincident with a Cartesian coordinate system. The SCARA or selective compliance assembly robot arm has two parallel rotary joints to provide compliance in a selected plane. The articulated robot has three or more, typically six, rotary joints placed in series with their interconnecting links. The parallel link robot is characterized by links that form closed loop structures shown with prismatic joints, but can also have revolute joints such as the Delta robot (Fig. 54.5) (pictures courtesy of Güdel, ADEPT, ABB, PI Physik Instrumente)

Category	Gantry (or Cartesian)	SCARA	Articulate	Parallel
Robot main axes structure	 3 prismatic joints	 1 prismatic and 2(3) revolute joints	 3 revolute joints	 Typically with 3, 4 or 6 prismatic axis
Workspace shape				
Technical example				

machines (SKMs), while the last is a parallel kinematic machine (PKM). To obtain maximum stiffness, again for a certain minimum level of cost, the end-effector is better supported from different directions, and here the PKM has significant advantages. On the other hand, if high stiffness (but not low weight and high dexterity)

is the main concern, a typical computerized numerical control (CNC) machine (e.g., for milling) is identical in principle to the gantry mechanism. There are also modular systems with servo-controlled actuators that can be used to build both robots with purpose-designed mechanisms.

54.4 Typical Industrial Robot Applications

Out of the many possible uses of industrial robots selected case studies on high-potential robot applications will be briefly described. Typical associated enabling technologies will be depicted.

54.4.1 Handling

Handling in robotics comprises numerous processes such as grasping, transporting, packaging, palletizing, and picking. As seen in Fig. 54.8 handling is the largest

robot application field which is found in all branches of manufacturing and logistics. A central feature and major challenge in the engineering of robotic handling systems is the design of the gripper and associated grasping strategies given the physical properties of the workpiece, throughputs, and uncertainties regarding object geometry and location. Current high-potential application of robot handling systems are: tending of CNC machines for workerless shifts [54.29], palletizing, and lifting of objects for ergonomic reasons or

Fig. 54.9a–d Units of sausage are cut from strings, then placed into the thermo-formed cavities before applying lidding. The coordination of the robots and the optimization of the picking frequency require a selection of the best path for each robot. Missed sausages are fed back on the conveyor for another try. The shown 4-DOF parallel robot reaches cycle times of 1–3 Hz and can move payloads of up to 8 kg (courtesy of robomotion, Germany)

Fig. 54.10a–d Lightweight customized vacuum gripper (0.75 kg mass) through additive manufacturing. Cookies are delivered continuously on a belt, grasped from the belt, and batches of eight are put on a blister matrix before final packaging. The gripper's spacing is pneumatically actuated and its rotation through the parallel robot's central rotational axis (courtesy of robomotion, Germany)

when limitations specified in load handling regulations are exceeded [54.30], for reasons of cleanliness as is typical in the food, pharmaceutical, and semiconductor industries [54.31–33], avoiding monotonous work and psychological strain, and ensure logistics quality through workpiece or object tracking [54.34]. In the following, two use-cases of material handling will be highlighted, each in a different industrial domain, and based on specific industrial robot type and enabling technologies.

Food Handling

The food sector is claimed to have significant potential for the application of robots as fundamental change to productivity, product quality, and worker ergonomics can be achieved [54.35]. In food automation, *untouched by human hand* entails critical requirements for robot automation such as the need for hygienic design, operational speed, ease of programming, and cost. In the past, these requirements had been difficult to achieve due to high throughputs, therefore requiring rapid grasps and fast robot motion, robust sensing for detecting object locations on conveyor belts. High speed at high flexibility apparently is a key in the indi-

vidual handling of food objects. Therefore, fast SCARA and parallel robots have found wide acceptance in this field.

An example of a packaging line in food production is depicted in Fig. 54.9 where cut mini salamis are delivered in four streams per conveyor belt in random sequence. The positions of the sausages on the translucent belt are determined by a computer vision system. The robot picks the sausage from the measured position sequentially until the gripper holds three sausages which are then placed into cavities. With four parallel robots a maximum pick rate of 600 sausages per minute can be processed. Key of the application is its high-speed 2-D (two-dimensional) computer vision system which feeds the robot's path planning for collision-free picks at a minimum loss rate of unpicked salami [54.37].

Recent efforts have led to customized designs of gripper systems through 3-D (three-dimensional) printing (additive manufacturing) which for instance includes actuation through pneumatically driven bellows and low-wear metal joints. An example of a highly actuated gripper based on 3-D-printing for use in food handling is depicted in Fig. 54.10. Additive manufac-

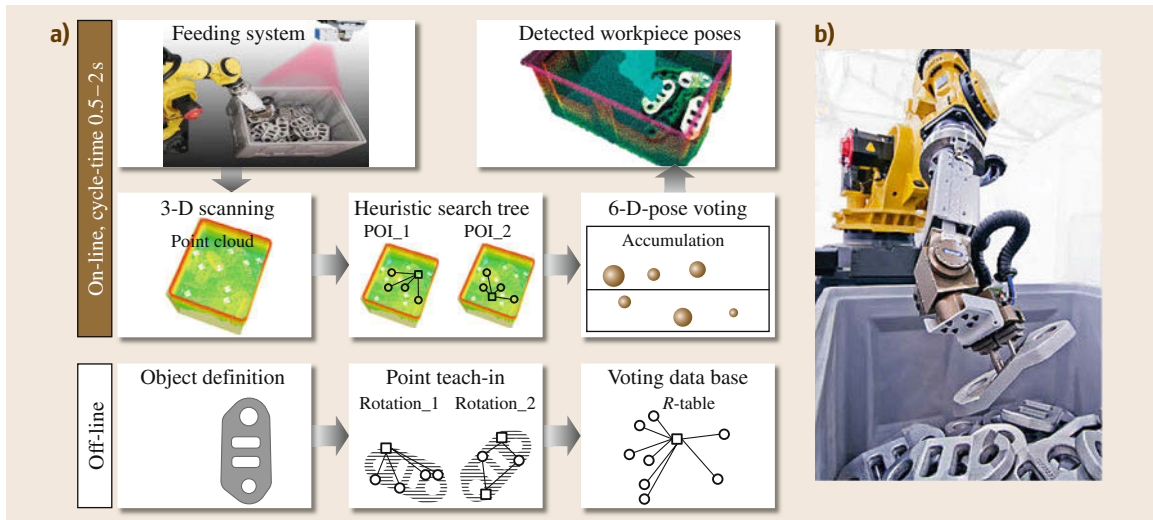

Fig. 54.11a,b Procedure of a bin-picking method [54.36] (a) and gripper with additional degree of freedom for reaching deep into bins (b). Depicted is a 2-D laser scanner on a swiveling unit for acquiring the point cloud in parallel to the robot's motion. The object detection itself consumes 0.5–2 s and is less time critical than the robot's motion and grasps

turing processes seem to be perfectly suited to achieve higher flexibility in manufacturing automation [54.38]. Numerous materials have become available for different additive manufacturing processes so that even specific manufacturing requirements can be matched. Initial doubts about gripper durability have been dispelled: lifetimes of more than 10 million load cycles for robot grippers manufactured on the basis of laser sintered polyamide have been reported.

Bin-Picking

Generally, industrial practice in robot workcell planning aims at finding a compromise between reducing the variation of the workpiece location and the cost of sensor systems to compensate for residual variation or uncertainties. Today, nearly all parts arrive at robot workcells in a repeatable manner, either being stored in special carriers or magazines, or by being transported and oriented by vibrating devices that allow the parts to settle into a predictable orientation for proper robot grasping. However, cost and flexibility requirements in manufacturing automation will result in reducing customized parts magazines to more universal carriers, containers, or conveyor belts. If randomly oriented on a conveyor belt or in a carrier, parts have to be properly identified and located so that the robot can produce an collision-free grasp.

The challenge of grasping partly or randomly ordered parts by robot has been referred to as bin-picking and has been investigated by numerous re-

searchers since the mid-1980s [54.39]. Even though an abundance of approaches has been presented, only recently bin-picking installations have found their way into daily manufacturing in significant numbers. Bin-picking algorithms follow a typical sequence of steps: initial point cloud data acquisition, object detection, pose estimation, collision-free path and grasp planning, object grasping, and object placement. Most methods in bin-picking assume known geometrical representations (a computer-aided design CAD-model) of the workpiece in question including the specification of admissible grasps for applying template-matching methods [54.40, 41]. Figure 54.11 depicts a variant of a fast template-matching method, which encompasses the following steps for detecting object poses:

- For detecting the scene (e.g., a carrier or box filled randomly with workpieces) typically laser-based sensor systems are used for acquiring a sufficiently dense point cloud. The object pose detection then is considered as a combinatorial optimization problem for which a construction heuristic is applied. For this heuristic tree search, a finite set of possible workpiece poses is initially derived from the search space.
- In order to use a decision tree, the elements of the search set are split into two components: The first component describes a point of interest (POI) in the search space which is part of the workpiece

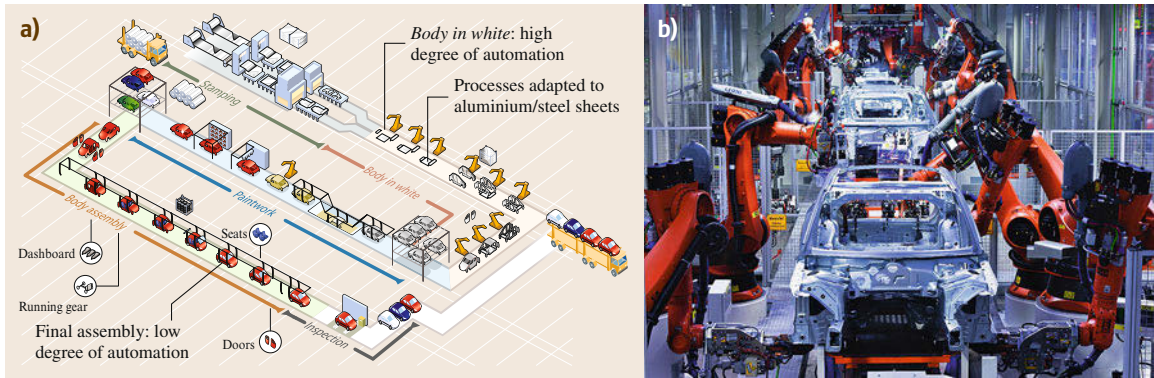

Fig. 54.12a,b Car production (a) usually follows the illustrated steps along the assembly line: Stamping of the metal sheet into plates, fixing and alignment of the plates on trays, spot welding, painting the car body, and final assembly of the car body (doors, dashboard, windscreens, power-train seats, and tires). Car factories can host over 1000 industrial robots working typically three shifts per day (courtesy of PSA Peugeot Citroën, Paris and Art Movies, Paris). The Audi plant in Ingolstadt Germany (b) is highly automated. The picture shows spot welding robots along the *body-in-white* transfer line. Trays carrying car bodies pass through the *robot garden*

surface. The second component describes possible workpiece poses relative to a [POI](#). The partial search quantities obtained thereby have a significant lower complexity compared to the original search set, since the points of interest can provide a constraint on relative workpiece poses, thus restricting their assumed freedom of movement.

- Typical tree search strategies such as best-first search can be used. In that case best-first search explores the search tree by expanding the most promising nodes first. These nodes are chosen according to a heuristic evaluation score, representing the estimated distance from the node to a solution.
- Final evaluation of the workpiece poses is provided by a six-dimensional (6-D) Hough voting procedure, i. e., a generalized Hough transform. The features used for Hough voting are sensor measurements located relative to a [POI](#). For all possible constellations of a sensor measurement relative to a point of interest, a probabilistic statement about possible workpiece poses can be made. Through the superposition of all probability statements, solution candidates can be formed, which are subjected to a statistical test based on a quality rating. The obtained quality rating along with a given level of significance is used in order to decide about the acceptance of a workpiece pose.

The method is able to locate three to four workpieces on average within 0.5–2 s, using a standard desktop computer. Moreover, robot grippers are equipped with a seventh axis to allow grasping parts

from corners of the bin. Furthermore, grippers should be formed in such a way that they may reach deep into the bin so that they offer only minimal collision volumes.

54.4.2 Welding

Welding is a manufacturing process that joins materials by applying heat, sometimes with pressure. Usually, workpiece material is melted at the process location often with additional filler material. Typical robot-based welding processes are spot welding, particularly in car body assembly, and gas-shielded metal arc welding ([GMAW](#)). With increasing compactness of laser sources and robot motion accuracy, laser welding is in the rise.

Manual welding requires skilled workers, as small imperfections in the weld can lead to severe consequences. Furthermore, welders are exposed to hazardous working conditions (fumes, problematic ergonomic working positions, heat, and noise) so that the use of robots has become beneficial in [GMAW](#) processes even for the smallest lot-sizes. Commonly, the automatic arc-welding process is based on a consumable wire electrode and a shielding gas that is fed through a welding gun. Modern welding robots are particularly suited through the following characteristics:

- Computer control allows efficient programming of task sequences, robot motions, external actuators, sensors, and communication with external devices such as welding sources.

Fig. 54.13a–c Offline programming of a spot welding workcell. (a) The robot workcell and the task execution are modeled on the basis of realistic robot models (geometry, kinematics, kinetics). (b) The shown laser tracker is a portable measurement system that relies on laser beams to accurately measure in a radial volume (accuracy of $\pm 10 \text{ ppm} = 10 \mu\text{m/m}$, up to 80 m in diameter, measuring rate up to 3000 points/s). If measured objects cannot be equipped with reflecting targets or reached by the tracker, handheld probes are tracked instead. (c) A tracker in use for interactively measuring the geometry of the robot workcell (courtesy of Leica, now Hexagon MI)

Fig. 54.14a–d GMAW welding of building trusses in lot-size one by robot. Illustration (a) shows the CAD drawing of a steel truss with relevant information for welding process, (b) one-half of the welding workcell with two welding robots working simultaneously on the truss when the neighboring truss on the other half is loaded or unloaded, (c) the laser-based seam finding and tracking sensors and (d) the welding robot (courtesy of Servo Robot, Canada; Goldbeck, Germany)

- Free definition and parameterization of robot positions or orientations, reference frames, and paths.
- High repeatability and positioning accuracy of paths. Typically repeatability is some $\pm 0.05 \text{ mm}$ and positioning accuracy is better than $\pm 1.0 \text{ mm}$. These values can be significantly improved through modern robot calibration methods [54.42].
- High speeds of the end-effector of up to 8 m/s for quick approach and depart motions.
- Typically, articulated robots have six **DOF** so that commanded orientations and positions in their workspace can be reached, which in the welding case means there is one **DOF** free for rotation around a rotational-symmetric welding tool. Additionally, workspace extensions by mounting the robot on a linear axis (seventh **DOF**) or even on mobile bases are common, especially for welding of large structures.
- Typical payloads range 6–150 kg. Higher load capacities are required for spot-welding guns (typically $> 50 \text{ kg}$) and their cable package.
- Programmable logic controller (PLC) capabilities such that fast input/output control and synchronizing actions within the robot workcell are accomplished.
- Interfacing to high-level factory control through factory communication networks.

Electric current sources, torches, and peripheral devices for automatic cleaning and maintaining the **GMAW** torch (anti-splatter, wire-cutting, tool changer, etc.) are offered by specialized companies. Often sensors are used to track welding gaps and measure weld seams either before or synchronously with the welding process, thus adapting the robot's trajectory in the presence of workpiece variation and distortion. Also, collaborating robots have been introduced where one robot fixes and moves the workpiece in synchronization with another robot carrying a welding tool so that the weld can be performed with the pool of molten metal horizontal.

Spot Welding in the Automotive Industry with Offline Programming

Car manufacturing has been one of the key drivers in the technical development of industrial robots as the precision handling of spot-welding guns was one of the first breakthrough use cases (Fig. 54.12) *body-in-white* (i. e., unpainted car body) assembly is mostly done by robots, very much in contrast to the final assembly which is

Fig. 54.15 A robot-guided tool for handling and processing limb material, in this case a self-adhesive seal for car bodies

dominated by manual work. Demands for faster cycle times have led to a concurrent and coordinated motion of the spot-welding gun and robot: the robot continues to move while the weld gun is simultaneously rotated about the electrode axis during welding [54.43].

Most of a spot welding robot's programming is done using offline programming (OLP) packages (Fig. 54.13). A library of robots, devices, and advanced CAD capabilities helps plan, program, visualize, and optimize layouts and complete production cycles under assumed manufacturing conditions. Robot programs can be generated and downloaded to robots workcells. A critical step is the calibration

of the robot workcell with respect to the simulations [54.44].

Arc Welding in Metal Construction

Normally steel constructions are designed using CAD programs that offer functions for GMAW-task definitions such as welding parameters, multipass seams, weld beads sequencing, etc. This information may be used for automatically generating welding robot programs, even in the case of lot-size one jobs.

As an example, the generation principle of a welding robot program is depicted in Fig. 54.14. Large-scale trusses of up to 15 m for large halls are welded-to-measure. The robot program is generated from the CAD drawing with process relevant information. Workpiece tolerances for example, induced by placing the steel components into the fixtures, by bending of the material under its own weight are compensated through active measurement. The robot-mounted sensor locates the weld seam by laser-based vision for shifting the generated programs in such a way that they match the actual weld seams. This calibration is automatically performed if expected and actual bead locations are within a range of ± 2.5 cm.

54.4.3 Assembly

Assembly in manufacturing describes the combination of subsystems or components to systems of a higher complexity through joining. Assembly in manufacturing comprises four process groups: joining, handling, controlling, and auxiliary processes (cleaning, adjustment, marking, etc.) [54.45]. The composition of these four functions may vary depending on batch size, product, and throughput: from assembly workcells to high-throughput assembly lines. Assembly processes form up to 80% of a product's manufacturing cost and this is where the greatest competitive advantage can be gained [54.46]. Therefore, optimization in assembly includes tightly interweaved aspects: Design

Fig. 54.16a,b Design of the KUKA iiwa: (a) Shape and (b) integration of joint mechatronics

for Assembly (DFA), workcell and assembly line design as well as logistics and manufacturing organization [54.12]. Early on, industrial robots were used in assembly automation, particularly in high-throughput manufacturing lines (Fig. 54.4). However, robots are increasingly used in highly flexible workcells and will enter agile lean manufacturing workplaces as versatile tools at the hands of the human worker. In the following, selective use cases of robots in assembly will be

described by detailing on specific enabling technologies.

Assembly of Limb Material

Numerous assembly processes include handling of limb materials such as rubber hoses, wire harnesses, etc. that have to be fixed in position in order to be joined (Fig. 54.15). Obviously stabilizing the material and securing process quality often result in ingenious grip-

Fig. 54.17 Set up and implementation of a centrifugal clutch assembly for a chain saw with a sequence diagram depicting the consecutive steps until tightening the clutch. Through the robot's torque sensors in each of its links and an appropriate kinematic and dynamic model, the resulting forces at the tool tip are controlled

per designs involving additional actuation and sensing functionalities.

An example is the automatic application of self-adhesive seals as they easily lose their shape and can be stretched or compressed. Since manual application of adhesive seals to vehicle bodies or doors is sensitive and ergonomically problematic a robot-guided tool has to secure bonding of the material's surface to the car body. The seal material is fed from a roll under correct tension and the tape, which covers the adhesive, is removed and stored in a small tank. At the tip of the tool a laser sensor follows the car body or door contour and an actuated roller produces a continuous normal force on the seal. Both the laser sensor and roller's motion are translated into a tension free motion of the robot. In addition, a magazine on a flange ensures that the seal is correctly tensioned and a material reserve for one car door is provided [54.47].

Here, the robot acts as slave to guide a tool which acts as both measuring unit and precision actuator with own master controller. Further efforts aim at embedding rich sensor and control modalities in the robot to account for complex process control based on tactile and geometric information.

Advanced Robot-Based Assembly Process Control

Automation of advanced assembly processes depends on physical contact between the joined workpieces. For this contact formation to be controlled a robot should offer compliant motion control which is a control method that modulates robot position and velocity

based on measured or estimated joint torques or contact forces [54.48]. Subject of intense research efforts for a long time application packages for compliant force control in industrial robots which fulfill requirements regarding versatility, robustness, and ease of use in programming have become available during the last ten years [54.49]. The solutions are commonly based on a 6-DOF force-torque sensor which is attached to the robot flange.

The fully torque-controlled DLR (Deutsches Zentrum für Luft- und Raumfahrt) lightweight robot broke new grounds as its 7-DOF redundant kinematic structure, torque sensing in every joint and a variety of compliance modes allowed difficult assembly tasks with complex contact formation during the joining process [54.15]. DLR and KUKA managed to successfully go the strenuous road from the original LBR invention, an idea made manifest in 1991, to a product, first applied in research and predevelopment of new industrial manufacturing concepts in a series of development steps: KUKA LBR3 (2006), LBR4 (2008), and LBR iiwa (2012) [54.25]. Figure 54.16 depicts the integrated mechatronic design of a joint with its unique joint-torque measurement.

To simplify the programming of complex joining processes several assembly subprocess modules were developed of which three are depicted in Table 54.2: the search for contact formation and the execution of two typical joining motions (peg-in-hole, toothed gear joining).

Figure 54.17 depicts a scenario of a force-based centrifugal clutch assembly for a chain saw. The robot

detects and locates the clutch workpieces on a tray by vision sensors. Now the grasped workpiece has to be joined and tightly screwed onto the shaft. In this case the robot's tactile capabilities and compliant behavior are used to achieve a robust and quick assembly. Once a rough shaft center position estimate is acquired by the robot's vision sensor, the robot approaches to this position and starts performing a search pattern until contact detection. The peg-in-hole process is followed by a screw-in motion for tightening the clutch. Alternative designs may be based on 6-DOF industrial robots with a wrist-mounted force-torque sensor to measure process-induced forces on the robot, or simply estimate the forces from the motor torque control [54.50].

The sequence diagram shows a simplified execution trace of a spiral search of a circular shape. Listing 54.1 lists part of the Java code in the KUKA Sunrise control system which identifies the three parts of the compliant assembly: main function, spiral search until collision, and border walk.

Listing 54.1 Extract from the code controlling the sequence of the centrifugal clutch assembly

Main Program:

```
Frame rough = camera.detectAssemblyTarget(); // Retrieve rough position from stereo vision
// Move robot at 30 mm/s. Linear motion. Stop if force > 20 Newton
ForceCondition forceCond = new ForceCondition(robot.getDefaultMotionFrame(), 20);
robot.move(lin(rough).setCartVelocity(30).breakWhen(forceCond)); // First approximation
Frame target = spiralSearch(rough, forceCond); // Obtain the assembly target
assemble(Target); // Assembles the shaft at the given position
```

Search Module. Returns the assembly target:

```
Frame spiralSearch(Frame rough, ForceCondition forceCond){ // Spiral search until collision
for (double phi = 0; phi < 10.0 * pi; phi +=pi / 90.0){ // 5 loops, 2° step
    Frame spiral = rough.copy();
    Double radius = max_radius * phi / (10.0 * pi);
    spiral.setX(rough.getX + Math.cos(phi) * radius);
    spiral.setY(rough.getY + Math.sin(phi) * radius);
    robot.move(lin(spiral).setCartVelocity(30).breakWhen(forceCond));
    if (motion.getFiredBreakConditionInfo())return findCircleCenter(); // It collides
}
return null; // Target not found}
```

Border walk to find shaft center:

```
Frame findCircleCenter()\textbraceleft // Calculates the center of a circular shape
ArrayList contact = new ArrayList<Frame> (); // Stores frames where collisions take place
do{
    Frame next = getNextFrame(robot.getForce());
    // Force feedback combined with search pattern such as a grid produces next frame

    robot.move(lin(next).breakWhen(forceCond)); // Move to next position, if possible
    if (motion.getFiredBreakConditionInfo()) contact.add(robot.getDefaultMotionFrame());
} while (!areEnoughContacts(contact)); // Until enough contact points to identify center
return getCircleCenter(contact); // Circle center can be determined with three points
}
```

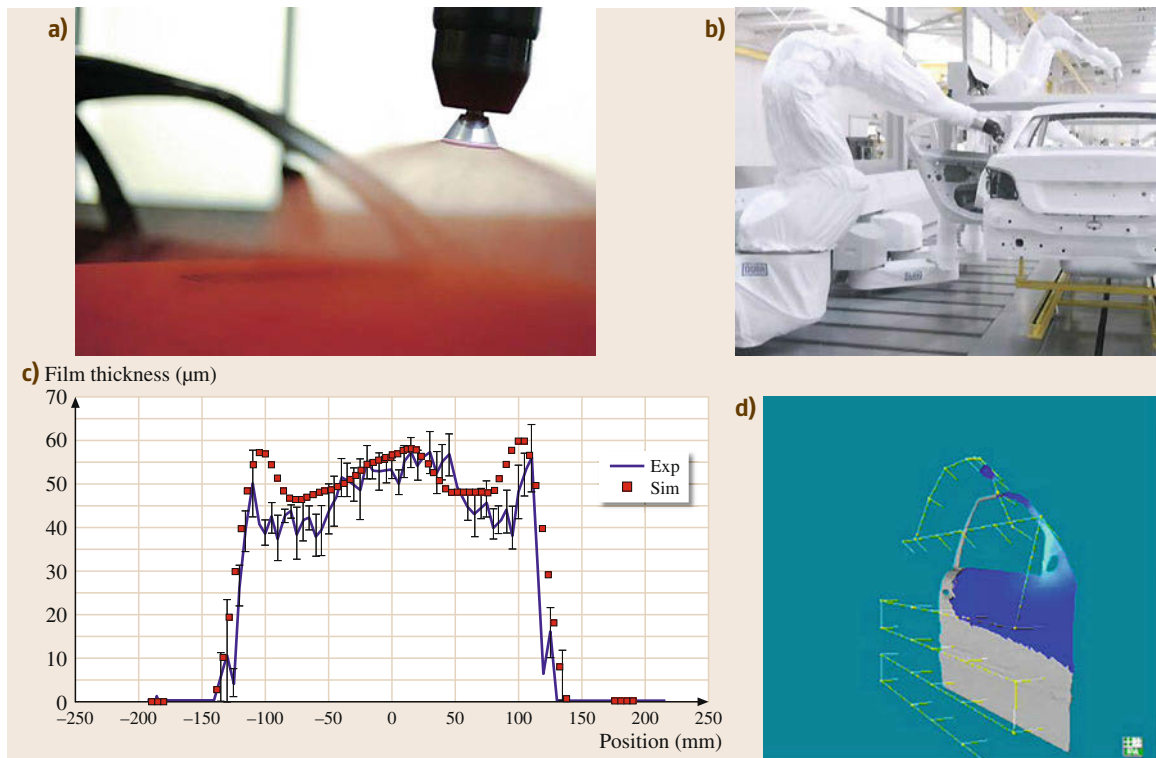

Fig. 54.18a–d High-speed rotating atomizer and a multirobot workcell for car body painting. **(a)** A Dürr EcoBell2 paint gun which atomizes the paint material at the edge of the rotating bell disk by centrifugal forces. All current paint materials such as solvent-based or water-borne paints can be used in car production. **(b)** Multiple robots work in parallel for optimal throughput and accessibility of the car body. Most of the programming which includes the synchronization of the robots is performed offline, also with respect to optimal coverage of the painted surface. **(c)** Simulation of the painting process is critical for achieving highest yields (e.g., minimal overspray, uniform paint deposition, etc.) **(d)** Results from simulations for optimized program generation are shown (courtesy of Dürr, Fraunhofer IPA, Stuttgart)

54.4.4 Painting

Hazardous working conditions for human operators motivated Trallfa, a Norwegian company, to develop simple spray-painting robots in 1969, particularly for spraying bumpers and other plastic parts in the automotive industry. Initially pneumatically driven for anti-explosion reasons, today's robot designs are fully electric. They also have hooks and grippers to open hoods and doors during the painting task. Hollow wrists that house gas and paint hoses allow fast and agile motions. Spray guns for robots have evolved dramatically for delivering uniform quality using as little paint and solvent as possible and also for switching between different paint colors. Originally spray-painting robots replicated movements copied from human workers. Most of the programming for robot painting today is done offline as state-of-the-art programming systems offer integrated process simulations to optimize paint deposition, thickness, and coverage (Fig. 54.18). The simulation of the

process is quite complex as different effects are taken into account such as turbulent flow field between atomizer and target, static electrical field between rotating bell disk and target, charging of the paint droplets at the bell, space charge effects due to the flow of charged paint droplets, and Coulomb forces acting on the droplets [54.52].

54.4.5 Processing

Material removal processes such as grinding, deburring, milling, and drilling are increasingly carried out by industrial robots with serial kinematics as they combine dexterity, versatility, and cost-effectiveness. The employed process tools are often combined with passive compliance or active force control as the workpiece geometry commonly exhibits tolerances in geometrical or material properties [54.53]. However, robot accuracy (± 0.5 mm range) compares poorly to values in the ± 0.01 mm range of typical machine

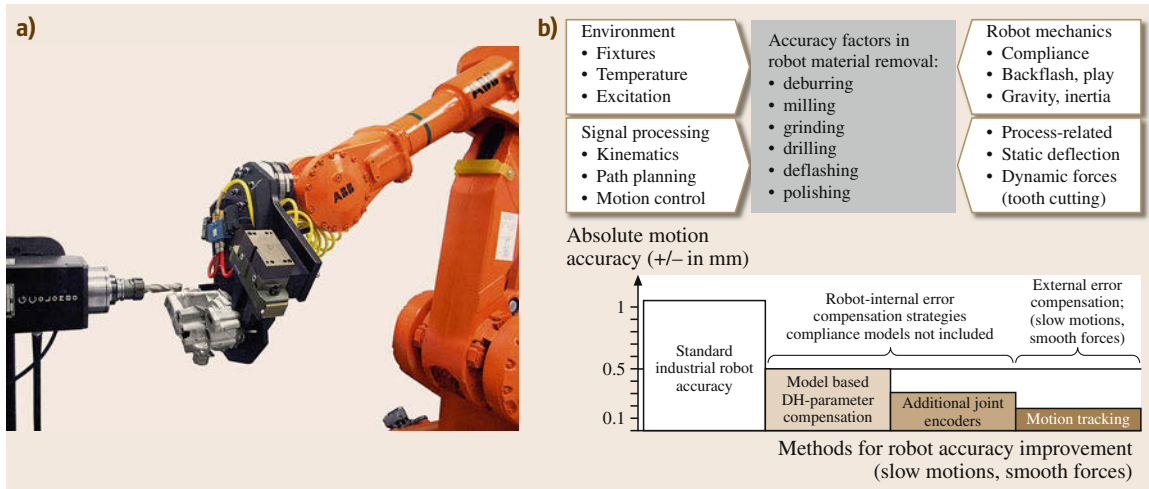

Fig. 54.19a–d For small-to-medium-sized parts, a preferred configuration is to have the part grasped and guided by the robot relative to the fixed spindle. **(a)** The robot's gripper is mounted on a force–torque sensor to measure and limit process forces. For machining the edges of the workpiece (deflashing) the machining software package provides a machine-learning technique for optimising the motions [54.51]. **(b)** Influences on accuracy in robotic machining and methods for robot accuracy improvement. Still typical machine tool motion accuracies are in the order of ± 0.01 mm or better (courtesy of ABB, Fraunhofer IPA)

tools [54.54]. The lower eigenfrequencies and damping coefficients of mechanical structures should be as high as possible for precision: The lower eigenfrequencies of milling machines are in the range of 50–100 Hz as compared to 20–30 Hz for typical industrial robots [54.55, 56]. Figure 54.19 depicts the factors that affect the robot's accuracy in typical material removal applications. Figure 54.20 shows first eigenfrequencies, damping, and stiffness in Cartesian

space. These characteristics are essential for the design of machining processes and resulting workpiece quality. More robot-guided processes such as laser welding and laser cutting depend on achieving similar accuracies.

Robot position accuracy results from geometric error sources (deviations between actual robot structure and assumed Denavit–Hartenberg (DH) parameters) and nongeometric parameters (compliance of the me-

Table 54.3 Characteristics of computerized numerical control (CNC) and robot controller (RC)

Category	CNC	RC	Interpretation
Targeted application	Machining, material removal	Handling, assembly	A CNC machine tool is single purpose; generally robots are universal machines
Motions	Path-based, complex contour-oriented	Point- or path-based and motion time-oriented	Extended look-ahead of CNC controllers allows detailed path description and adaption on $\gg 100$ via points (< 10 via points in most robot controllers)
Programming	On-site programming based on standardized programming language (G-code), ISO (International Organization for Standardization) 6983, use of computer aided manufacturing (CAM) tools	On-site teaching (teach pendant, editor) based on supplier specific languages, use of typical robot simulation environments	Whereas robots are traditionally programmed manually on site, CNC controllers use CAM technology to generate complex paths automatically based on CAD data
Command reading	Online interpreter, continuous loading of instruction	Initial loading of programs, which are usually interpreted, sometimes compiled)	Program size in robot controllers limited by memory, CNC interprets programs online, may execute an unlimited number of commands

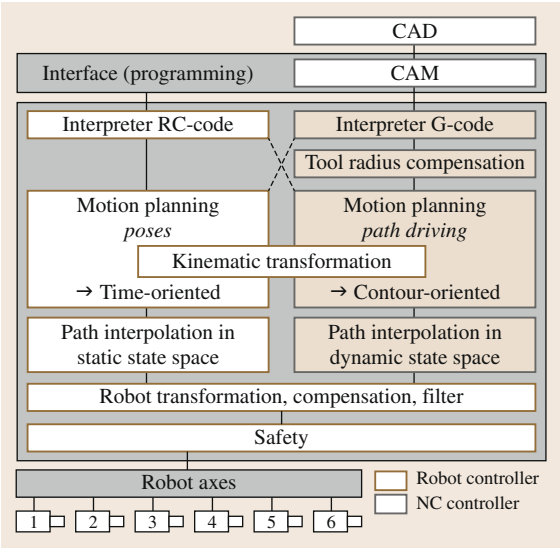

Fig. 54.21 Structure of an NC-kernel integrated into a robot controller (courtesy of ISG Stuttgart)

chanical structure and gear play). In order to reduce the impact of the nongeometric parameters several stepwise approaches can be implemented:

- In combination with force prediction or online measurements robot compliance can be compensated by means of joint stiffness models [54.57]. In

drilling applications additional encoders are sometimes mounted on the arm side of robotic joints in order to measure gear-induced joint compliance and backlash, or those effects can be estimated based on determined joint properties [54.58], so that a compensation can be achieved.

- In combination with the geometric error calibration accuracies of better than ± 0.2 mm for typical robots have been realized in larger robot workspaces of $3 \times 3 \times 2$ m³ [54.59].
- For higher accuracies further sensor and actuators systems have been introduced. Using optical tracking deviations of ± 0.2 mm have been demonstrated in steel [54.60]. With additional actuation deviations could be reduced to ± 0.1 mm [54.61].

Robot and CNC machine tool controls may have similar origins, but have taken different paths in developments over the years as depicted in the following Table 54.3.

Increasingly CNC controllers are used for robots in material removal applications for taking advantage of the well-established off-line programming tools in the CNC world and for improving motion accuracy of the robot for complex 3-D contours (Figs. 54.21 and 54.22. Modern robot controllers integrate so-called numerical control (NC) kernels which share components of the robot controller such as user interfaces, kinematic transformations, and safety functions.

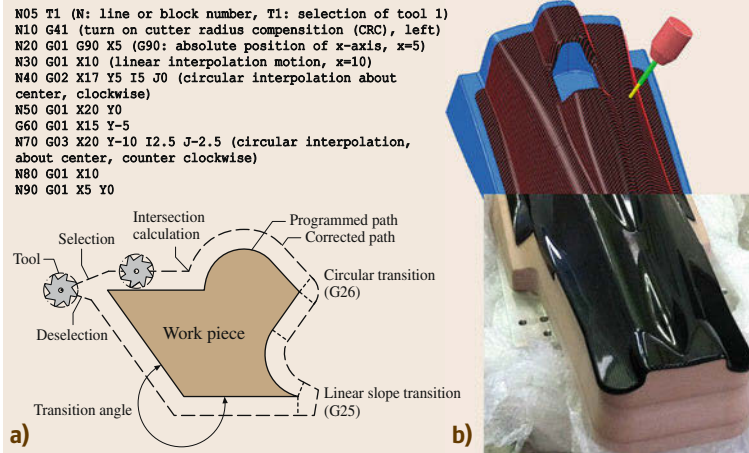

Fig. 54.22 (a) A simple CNC program (G-code, ISO 6983). A CNC program normally is machine independent and orients itself on the workpiece contour after processing. (b) Most CNC programs are generated automatically through CAM tools that transfer geometric information into executable G-code. The example shows generated tool trajectory generation for precision milling of a carbon fiber (CF) part and the finished workpiece (courtesy of Delcam, Birmingham; ISG, Stuttgart)

54.5 Safe Human–Robot Collaboration

Human–robot collaboration allows the combination of typical strengths of robots with some of the numerous strengths of humans. Typical strengths of industrial robots are high stamina, high payload capacity, precision, and repeatability. Strengths of human workers that are unmatched by any machinery comprise flexibility for new production tasks, creative problem-solving skills, and the ability to react to unforeseen situations.

However, industrial robots have a significant potential to harm humans. Therefore, standards for designing and operating industrial robot automation systems have been introduced and found international acceptance. Since 1999, efforts have been made to define measures, rules, and examples specifically for robots in collaborative modes.

54.5.1 Overview of Basic Robot Safety Standards

Machine safety standards provide guidelines for designing and operating any type of machinery. Their consideration is optional, but exhibits the straightforward way of verifying the fulfillment of the fundamental health and safety prerequisites of the Machinery Directive [54.63, 64]. Generally, safety standards are classified into three categories (Fig. 54.23):

- Type A standards: basic standards that define fundamental principles to achieve machine safety.
- Type B standards: generic standards that regulate either a specific safety aspect, e.g., separating dis-

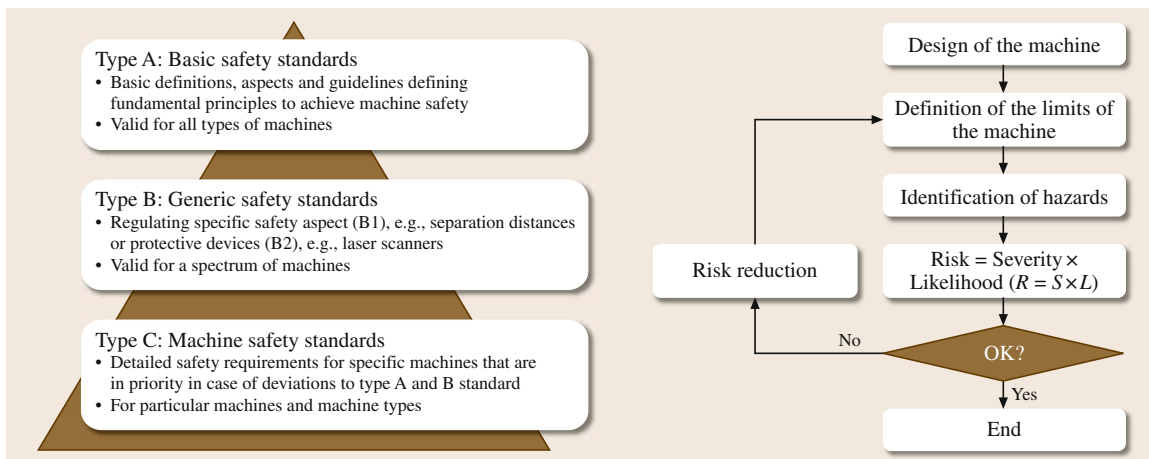

Fig. 54.23 Different types of standards and a simplified iterative risk assessment procedure. See ISO 12100 [54.62, Fig. 1 and 2] for a more detailed schematic representation of risk reduction process

- tances, or specific protective devices, e.g., optoelectronic protective equipment like laser scanners or emergency stop (ISO 13850), and are valid for a spectrum of machines.
- Type C standards: machine standards that list detailed safety requirements for a specific type of machine, e.g., industrial robots.

For robotic safety the following standards are of highest importance:

- ISO 12100 [54.62]: Type A standard listing general principles of machine safety, in particular the risk assessment process.
- ISO 13849 [54.65] and IEC 62061 [54.66, 67]: Type B safety standards governing the design of control systems with safety functions.
- ISO 13855 and ISO 13857 [54.68, 69]: Safety distances for separating and nonseparating safety equipment, e.g., fences, light curtains, and laser scanners.
- ISO 10218-1/-2 [54.5, 6]: Type C standards specifically covering safety of industrial robots and robot system integration.

For the setup of any robot installation, an iterative risk assessment process as defined by ISO 12100 has to be conducted. Its workflow as depicted in Fig. 54.23 starts with a functional and geometric design of the machine followed by the definition of the machine limits including spatial boundaries and boundaries regarding usage, e.g., typical tasks, operator qualification, and environmental conditions. The process continues with an identification of the tasks which are consecutively assessed on its risks. Methods for risk estimation are, for example, risk trees as presented in Fig. 54.24. Thereby, any individual hazard is rated on its risk level by quantitatively considering the potential injury severity, the

exposition to the hazard, and the possibility to avoid it. The risk estimation leads to a decision if all hazards have been adequately addressed in the machine design. If this is not the case, the machine design is modified to reduce the specific risk and the risk assessment process is repeated.

According to ISO 12100, measures to reduce risks need to be carried out according to the following priorities:

- Risk reduction through inherently safe design
- Risk reduction through safeguards and protective devices
- Risk reduction through information for use (e.g., work instructions, instructions to wear protective equipment).

The central safety standard family for robot safety is ISO 10218. Part 1 addresses the safety requirements of the robots, complemented by part 2, which focuses on the robot system, i. e., the complete integrated machine performing a production task. The second revision of part 1 and the first revision of part 2 were released in 2011 and replace any former robot safety standard, such as EN 775. These standards for the first time define *human–robot-collaboration* as a specific form of a robotic application in an industrial setting and provide guidelines for setting up such collaborative robot systems.

54.5.2 Types and Requirements of Human–Robot Collaboration

ISO 10218-1:2011 contains specific requirements on human–robot-collaboration. It defines four types of collaborative operations in which a human can collaborate with a robot in automatic mode, as depicted in Fig. 54.25. All controller functions for safe human–

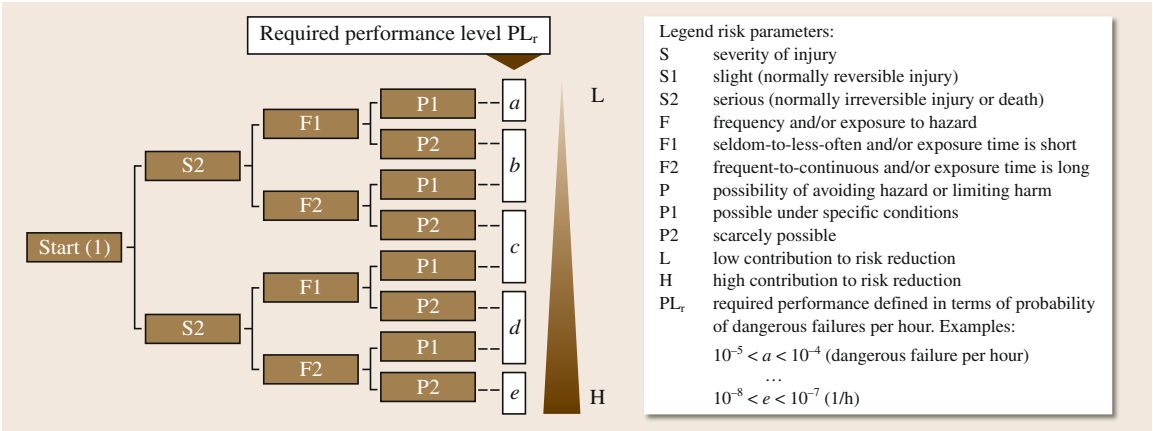

Fig. 54.24 Risk graph for determining required PL_r for safety function according to EN ISO 13849-1 (after [54.65])

Fig. 54.25a–d Modes of human–robot collaboration according to ISO 10218.

(a) Stop on access with automatic task resumption, (b) hand-guiding (c) separation and speed reduction, (d) monitoring and power and force limiting

robot collaboration have to comply with performance level PL_d with category 3 structures (ISO 13849-1) or SIL 2 (IEC 62061) if the safety assessment does not yield a differing requirement:

- Safety-rated monitored stop (Fig. 54.25 Type 1): The robot is stopped upon access of the human to the collaborative workspace with the robot drives still in control. A so-called safety controller, now offered by most robot manufacturers, assures the standstill of the robot. The robot task can be automatically resumed as soon as the human operator has left the collaborative workspace. Human and robot share the same workspace, but the robot does not move while the human is present.
- Hand-guiding (Fig. 54.25 Type 2): This type of operation implies a direct physical interaction between human and robot with full control of the human over the robot movement. The human guides the robot through a direct input device (e.g., a handle) at or near the end-effector while activating a three-position enabling device (three-position hold-to-run device). Thereby the position of the worker within the collaborative workspace is defined. A safety controller for delimiting the robot speed to a specified threshold is required. Hand-guiding in combination with graphic support through icons or 3-D simulation is in particular suitable for intuitive programming of industrial robots [54.70] during automatic mode of the robot.
- Speed and separation monitoring (Type 3): The relative speed between robot and human as well as their distance are actively monitored. If the human is present, the robot has to maintain a safe combination of speed and distance to the human to be able to stop any hazardous motion before a contact with the human may occur. Again safety controllers in conjunction with safe surveillance sensors (in-

cluding safe sensor data processing) are needed to supervise speed and position of the robot for human

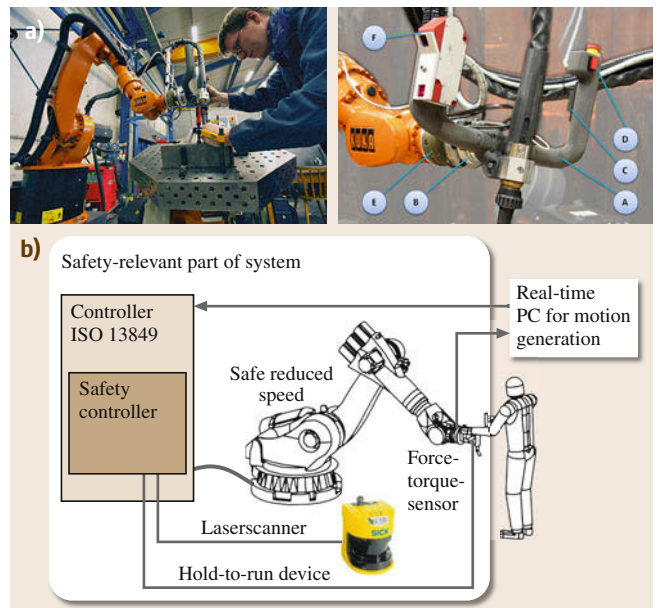

Fig. 54.26a,b Intuitive instruction of a welding robot by lead-through programming: (a) the worker guides the robot by a flange-mounted (B) handle (A) while pressing safety switches (three-position hold-to-run button) (C) on either side. The force exerted on the handle is measured by a force–torque sensor (E) and translated into robot motion. The seam tracking sensor (F) simultaneously measures the workpiece contour for precisely localizing and extracting weld seams. The recorded robot motion is visualized and edited in a simulation environment before task execution. (b) The safety relevant part of the system contains a three-position hold-to-run device, a laser scanner for safety monitoring during automatic program execution and a speed monitoring function during hand-guiding is an operational feature which does not have to be realized with a specific safety integrity level (courtesy of Fraunhofer IPA)

motion capturing. Currently, relatively few sensors in industrial automation offer this capability with the required safety integrity level. However, such systems will be available in the future, then being able to feature novel safety strategies for dynamic distance control [54.71].

- Power and force limiting (Type 4): The mechanical hazard potential of the robot is sufficiently reduced to allow a direct, physical interaction of human and robot without an additional safety controller. This is achieved by appropriately limiting collision forces through the design of the robot system such that in the event of a contact between the human and a robot biomechanical tolerance limits are not exceeded.

The ISO 10218 standards in their latest revision as of 2011 explicitly demand that speeds, distances, powers and forces are to be sufficiently limited, but does not give precise threshold values for these limitations. These threshold values need to be determined through risk assessment for a specific application that is foreseen with the robot system. Currently, the technical committee ISO/TC184/SC2 *Robots and robotic devices* develops a technical specification ISO/TS 15066 (in *committee draft (CD)* status of December 2015). It has been drafted to offer more guidance on the risk assessment for collaborative robots and will be released in the near future [54.72]. The procedure to achieve safety outlined in TS 15066 is new for machine safety (not only for robot safety) and is expected to make its way into further standards, especially into the second revision of ISO 10218-2.

For the first time, ISO/TS 15066 introduces tolerance values for the physical strain of the human body. These strain thresholds include maximum forces and maximum pressures for different body parts that can be sustained without suffering from pain or even injury. The risk assessment process involves determining body regions with risk of contact depending on the specific applications and workflows. Based on this information, it can be proved experimentally or in simulation that the given severity threshold values are not exceeded due to limited mechanical or robot control parameters [54.73, 74]. The technical specification aims at transforming highly complex biomechanical injury thresholds into controllable robot performance limits. One of the principles used for dynamic collision analysis is based on the fundamental robot dynamics theory which enables the representation of the reflected inertia of a robot system at any point along the robot structure. Drop-test results from medical injury assess-

ment have been made available for designing robot controllers [54.75].

Part 2 of the ISO 10218 standard provides guidelines regarding the aspects that need to be taken into account during robot workcell setup and system integration. It states the need not only to assess the robot itself, but to take into account the complete application, particularly the end-effector, process, environment, and typical work tasks. This is of special importance for collaborative human–robot operation. As the application always needs to be taken into account, it is not possible to design a *safe robot*, but only to provide robots that are equipped with safety features for setting up a safe collaborative operation.

54.5.3 Examples of Human–Robot Collaboration

In the following, two examples for human–robot collaboration are given.

Intuitive Instruction of a Welding Robot by Lead-Through Programming

Figure 54.26 presents a robot welding workcell which is designed for small batch size production. An intuitive teaching process implementing *hand-guiding* according to ISO 10218 (Type 2 in Fig. 54.25) significantly speeds up robot programming time. The presence of the human during the collaborative operation is monitored via a laser-scanner activating safety zones and safe speed reduction of the robot safety controller during the hand-guiding operation. The recorded motion can be executed automatically after switchover as soon as the human is out of the collaborative workspace.

Collaborative Assembly of Battery-Cases

In this case, sensitive tasks are carried out by the human, while strenuous tasks are executed automatically by a small payload robot (Fig. 54.27 for the cell design). Thereby, the safety concept comprises the requirements for *speed and separation monitoring* (Type 1 in Fig. 54.25) from ISO 10218 and involves two light curtains with a signal processing on a safety PLC and a robot with a safety controller. Switchover between the safety zones is activated upon detection of human presence in a collaborative workplace area. Each safety zone statically monitors the minimum possible distance to the robot's active workspace thereof deriving the maximum possible robot speed. Such a system reduces space requirements for a robot installation while enhancing the flexibility of the assembly process due to the collaborative nature of this assembly process.

Fig. 54.27 The robot's workcell is divided into three segments by two light curtains which trigger in which area the robot works at lower velocity when collaborating with the worker in the collaboration spaces

54.6 Task Descriptions – Teaching and Programming

Although desirable, a robot cannot be instructed in the same way that one would instruct a skilled human worker how to carry out a task. With skilled human workers knowing the applications, devices, processes, and the general requirements on the product to be manufactured, we would only need to summarize what needs to be done. Humans have, with or without awareness thereof, extensive knowledge about motions, physical effects, cause–effect relationships, learned procedures, etc., and they maintain such knowledge for their own good. A human is skilled because physical capabilities are combined with reuse of that learned/maintained knowledge, and the purpose of the manufacturing operation can be explained and understood.

Robots are not capable of performing such knowledge-based behaviors in a productive manner. Instead, instructions have to be quite explicit and motion oriented, and even motion planning is rarely used since it is difficult to encode much of the required background knowledge. We could aim for programming principles that resemble instructing a (totally) unskilled worker, telling precisely how every aspect of the task is to be performed. Such an explicit way of instructing the robot then should be human friendly, but the performance requirements motivated by productivity needs imply that methods for defining the task need to reflect machine/robot properties considering product data and production processes. Existing approaches include:

- Manually guiding the robot to the positions of interest, or even along the desired paths or trajectories if human accuracy is enough (Fig. 54.26).
- Having simple ways to make use of CAD data whenever available (Fig. 54.13).
- Using different complementary modalities (paths of communication between the human and the robot), such as pointing devices and 3-D graphics.

- Choreographing the task movements, for instance loops and conditions, without requiring extensive programming competencies.
- Means of describing acceptable variation, e.g., acceptable deviations from the nominal path or POI.
- Specification of how external sensing should be used for path adaptations or for handling unknown variations.

Most of these items still mean that the robot is rather dumb, and the knowledge of solutions is maintained among human experts. Consequently, robots are time-consuming and hard to instruct for productive industrial tasks, and the created solutions are not reusable since the knowledge is not explicitly represented in a way that is useful for the robot. To embody knowledge in the robot system is the way to make task definition more efficient, which can be better understood if we review the origins and the progress so far. Initially, mainly during the 1970s and 1980s, there were some painting robots that could be programmed by manual guidance. This was possible due to the following abilities:

- Applications such as painting permitted the use of a lightweight arm, including the end-effector, possible balanced with respect to gravity if needed.
- The accuracy requirements were (compared to today) modest so it was possible to use back-drivable drive trains and actuators, and the definition of the motions could then be done manually by the operator moving the end-effector along the path. The recorded poses, including the timing/speed information, defined the programmed motion.
- Since no inverse kinematics was needed during programming or real-time operation, it was not a problem from a computing point of view to use arm kinematics without singularities in the workspace.

- The requirements of optimality of painting motions were also modest, compared to recent years when environmental conditions (for nature and workers) called for minimal use of paint.

It is often referred to as an inevitable problem that there are singularities to be handled within the workspace. However, to simplify the kinematics and its inverse from a software point of view (e.g., during the 1980s considering the power of the microprocessors and algorithms available at that time), robots were actually designed to have simple (to compute) inverse kinematics. For instance, the wrist orientation was decoupled from the translation by the arm by using wrist axes that intersected with the arm axes. The resulting singularities within the workspace could be managed by restrictions on wrist orientations, but an unfortunate implication was that robot arms were no longer back-drivable (close to the singularities) when designs were (due to engineering and repeatability requirements) adopted to standard industrial controllers. Then with the development of microprocessor-based industrial controllers and the definition of motions based on jogging (manual moves by for instance using a joystick) and CAD data, the means of robot programming became closer to computer programming (extended with motion primitives).

Robot programming languages and environments have traditionally been separated into online programming (using the actual robot in situ) and OLP (using software tools without occupying the robot). With the increasing power of OLP tools, their emerging ability to connect to the physical robot, and the increasing level of software functions that are embedded into the robot control system, online programming is now unusual, except to verify and manually adjust programs generated offline. Of course, it is economically important to minimize downtime for robot programming, and advanced sensor-based applications may be too hard to develop without access to the true dynamics of the physical workcell for fine-tuning. Nevertheless, robot languages and software tools must provide for both methods of programming.

Even though robot languages from different manufacturers look similar, there are semantic differences that have to do with both the meaning when programs are running (the robot performing its operations) and the way the robot is instructed. The need to ensure that existing robot programs can operate with replacement robots and controllers, and also to make use of existing knowledge in robot programmers and incorporated into OLP software, requires manufacturers to continue supporting their original proprietary languages. Features such as backward execution (at least of motion statements) and interactive editing during inter-

pretation by the robot (in combination with restrictions to make the programming simpler) also make robot languages different from conventional computer programming languages.

During the last decade and in current developments, the trend has been to focus on the tool (robot end-effector) and on the process knowledge needed for the manufacturing process, and to let the operator express the robot task in such terms. This development results in a need for an increased level of abstraction to simplify the programming, reflecting the fact that the so-called robot programmer knows the production process very well, but has quite limited programming skills. To understand why such a high level of abstraction has not come into widespread usage, we may compare this with the early days of industrial robotics when there was no kinematics software built into the controllers, and hence the robots were programmed via joint-space motions. (Kinematics here deals with the relation between robot motors/joints and the end-effector motions.)

Built-in inverse kinematics permits tool motion to be specified in Cartesian coordinates, which is clearly a great simplification in many applications. That is, the robot user could focus more on the work to be carried out by the robot and less on the robot itself. However, robot properties such as joint limits cannot be neglected. Until the beginning of the 1990s, robots did not follow programmed trajectories very well at high speeds or accelerations, and full accuracy could only be achieved at low speed. Modern robot systems with high-performance model-based motion control perform their tasks with much greater accuracy at high speed due to model-based control features (Chap. 6).

There are increasing opportunities to raise the level of abstraction to simplify the use of robots even more by encoding more knowledge about the robot, tools, the process, and workcells into control systems. This is a gradual development with possibilities depending on the application; when knowledge is not encoded the robot programmer needs to be more aware of robot properties and how to handle them. Reasons for not including such knowledge typically lie in the fact that it is simply too difficult to do so or because the robot programmer does neither have the competence nor the tools nor reasons to do so. With reference to Table 54.4, the following example explains that type of trade-off and what it means in terms of centricity.

A machine part consisting of steel plates and pipes is to be manufactured by means of welding, and there is robot and process equipment available for production of this (and other) types of workpieces:

- A product-centric system would generate configurations and robot programs, and instruct the oper-

Table 54.4 Robot-related centricity, ranging from a high-level view of the work to be accomplished in terms of the product to manufacture, to a low-level robot motion view that, in practice, constraints what manufacturing operations can be performed

<div>User application</div> <div>↑</div>	<div>Robot constraint</div> <div>↓</div>	Product	Description of the final shape and assemblies of the workpieces, in terms of that product; the robot system plans the operations	
		Process	Based on known sequences of specific manufacturing operations, each of these is specified in terms of their processes parameters	
		Tool	The motion of the robot-held tool is specified in terms of programs or manual guidance; the user knows the process it accomplishes	
		Arm	The robot arm and its end-plate for tool mounting is programmed how to move in Cartesian space	
		Joint	For each specified location, the joint angles are specified, so straight-line motions are difficult; the robot provides coordinated servo control	

ator for whatever manual assistance that might be needed (e.g. clamping and fixturing). The system would determine the welding data such as the type of welding and how many passes for each seam.

- A process-centric system would instead accept input in terms of the welding parameters to use, including the order of the welds. The system would select input signals to the process equipment (such as what output voltage the robot controller should set such that the welding will be done with a certain current), and robot programs specifying the motions of the welding torch would be generated.
- A tool-centric way of programming would require the operator to set up the process manually by configuring the equipment in terms of their native settings, and appropriate tool data would be configured such that the robot controller can accomplish the programmed motions, which are specified by giving coordinates and motions data referring to the end-effector.
- An arm-centric system is similar to the tool-centric approach in that Cartesian and straight-line motions can be (and need to be) explicitly specified/programmed by the programmer, but extra work is needed since the robot does not support a general tool frame.
- A joint-centric style would be needed if one of the very early robot systems is being used, requiring a straight line to be programmed by lots of joint-space poses close to each other.

Thus, the question is, are you programming robot joint servos to make the robot provide a service for you, are you programming/commanding an arm how to move a tool, is it the tool that is made programmable by means of the robot, is it manufacturing services that are ordered by specifying the desired process parameters, or is it an intelligent system that simply can produce your product? Still today in industry, there are reasons

to think and program considering all five levels, although the tool-centric alternative is kind of a baseline. Hence tool-data needs to be maintained in the robot program, as in the next example below.

As a final goal related to the product-centric view, so-called task-level programming is desirable. This has been a goal since the 1980s, and implicitly also since the very beginning of robotics. It would mean that the user simply tells the robot what should be done in common terms and the robot would know how to do it, but it would require extensive knowledge about the environment and so-called *machine intelligence*. The need for extensive modeling of the environment of the robot is well known. Sensing of the environment is costly, but in an industrial environment it should only be needed occasionally. Modeling has to encompass full component dynamics and the limitations of the manufacturing process. With these difficulties, task-level programming is not yet achievable in practice. If we limit our domain, however, such as to machining where motion planning is already used for so-called machine tools, generating the robot programs from product descriptions is feasible since the process (with tolerances due to robot compliance) is modeled.

As indicated in the application examples, it is now common practice to generate robot programs from geometric data in **CAD** files. That is, the **CAD** application could be the environment used for specifying how the robot should perform the required operations on the specified parts, which is the **CAM** part of **CAD/CAM** (Computer Aided Manufacturing, often in term of a back-end to the **CAD** system, and hence usually not explicitly referred to). **CAM** is not quite task-level programming since human operators do the overall planning. **CAD** software packages are powerful **3-D** tools that are very common among manufacturing companies. Consequently, using these tools for robot programming is desirable since the operator may start the **OLP** of the necessary manufacturing operations us-

ing the 3-D model of the product, even before selecting a robot.

There is an ongoing competition along the so-called vertical integration from product data down to machine operations, including at least the following three approaches:

- CAD providers increasingly offer advanced robot-aware functions, thereby expanding their field of service and expertise from a higher (CAD) to a lower (robot) level. An example of a robot-aware CAM system is depicted in Fig. 54.22.
- Robot providers have developed programming tools with CAD data import and various motions planning modules, and thus, expanded their offerings to higher levels. One such software is shown in Fig. 54.29.
- A further development is to include a CNC kernel into the robot controller, as suggested in Fig. 54.21, making the robot behave as a CNC machine.

These approaches as such are more complementary than competing, with the competing stakeholders presently exploring what benefits can be gained for customers and business in each type of application.

Listing 54.2 Example pick-and-place operation in the ABB robot programming language Rapid

```
PROC PickInPallet()

PROC Release()
  SetDO doGrip, 0;
  WaitDI diGripped, 0;
ENDPROC
```

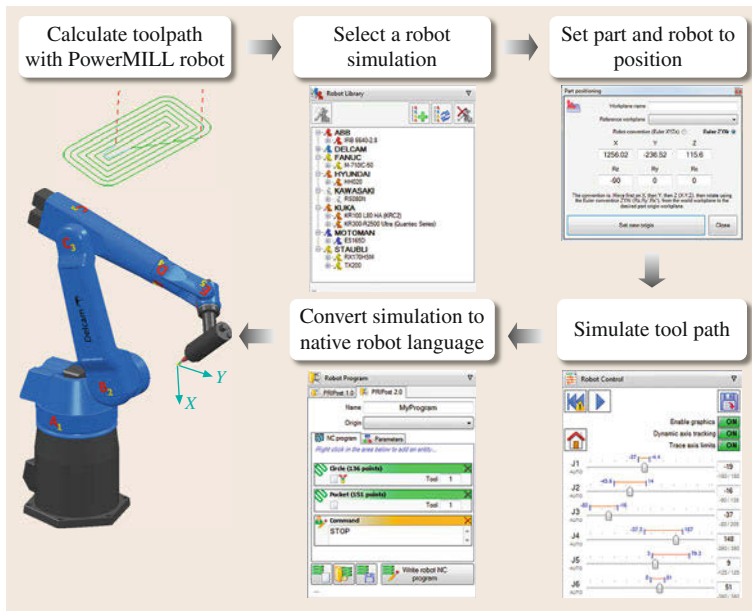

Fig. 54.28 Workflow according to the PowerMILL software from Delcam with its robot module. Note that step 4 includes also simulation of robot properties such as closeness to singularities

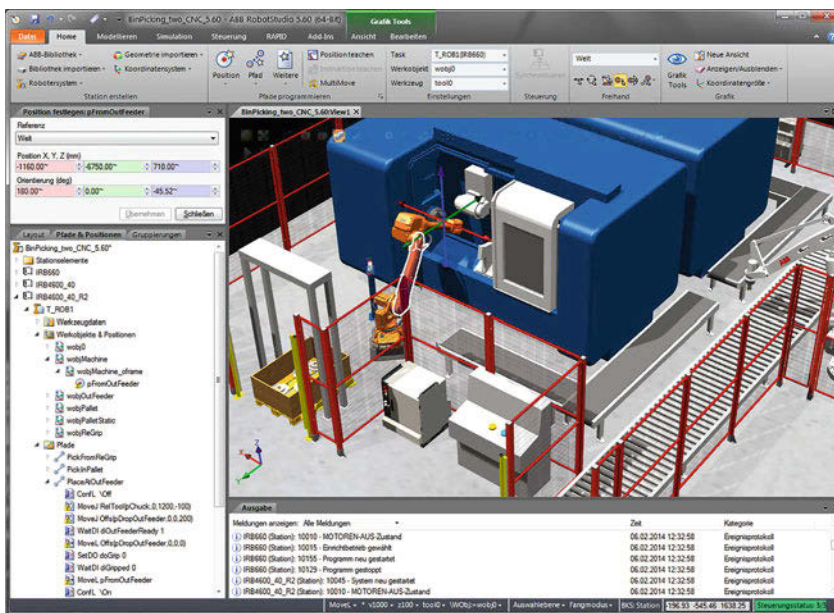

Fig. 54.29 Robot programming environment, with a virtual controller (console to the lower right) for each robot including the model-based embedded control software compiled for the personal computer (PC). To the left there are the instances of all objects depicted as a tree structure, ranging from complete machines down to the bits of the I/O signals

At step 5 in Fig. 54.28, the motion specification is generated and expressed in the native language of the robot. On the other hand, the tool path could be expressed in machine-independent, standardized G-code. A further step would be to integrate a machine tool interface and control into the robot controller which is depicted in Fig. 54.22. What approach to take is an area of current research and development (R&D) and business decisions, but most robots are programmed in their

own language only, since the needed system functions as a consequence of Table 54.4.

To exemplify task definitions based on a native robot language, consider the application depicted in Fig. 54.29, which includes bin-picking, handling, machine tending, conveyer tracking, and palletizing. Listing 54.2 lists a sample program with some of the functions from that application programmed in ABB's proprietary robot language Rapid. The program being

tool-centric shows in the tool argument of the Move statements, the *tGripper* that is a reference to the tool data including the tool frame. At the same time, it is arm-centric in the way that the execution of motions is performed per arm (with support for synchronized execution for multiarm robots), as expressed by the *MoveL* statements. Correspondingly, the *MoveJ* performs a joint-space motion.

Note that Grip and Release are in separate procedures where execution waits until a hardware acknowledged signal is obtained. For MOVE statements L denote Linear, J means Jointspace, functions Offs and RelTool compute target poses based on other determined poses (i. e., frames). The *v*-constants are velocities in mm s^{-1} , and *z*-constants (or fine) specify how close to the target pose the motion should be. DI refers to digital input and DO to digital output. The WObj is the work object, i. e., the specification of the base frame of the motions.

When programming motion behaviors like a search strategy, which could be considered being a motion primitive from an application point of view, use of the end-user language of that robot might not be the best option. Instead a computer programming language can be more appropriate as shown in Listing 54.1. In the ABB case, the strategies are implemented as part of an application package as for assembly, and the code is internally written in C (cannot be viewed or changed

by the user, but has optimized real-time performance) while the functionality is exposed to the robot user via special statements like FCRefSpiral [54.51] and more to accomplish the principles of Table 54.2. A variety of solutions are available for different robot brands [54.76].

Considering a complete setup with multiple robots, either with a few robots and some peripherals like in Fig. 54.9 or a complete manufacturing line as in Fig. 54.12, there are several robot programs that need to be programmed to work together and hence there is a coordination and complexity problem. A useful approach is to use a service-oriented approach, considering robots as servers providing services according to a set of programs that are exposed on the factory or production-cell network which means programming is done by:

- Building services (using several technologies) which are available, discoverable or not, remotely accessible by the application programmer
- Building applications that coordinate and use those services.

For such system to be programmable, however, the equipment (typically from different suppliers) has to be configured and interconnected according to the sometimes overlooked art of robot system integration.

54.7 System Integration

It is interesting to note that connecting different work-cell devices with each other, and integrating them into a working system, is hardly mentioned in the robotics literature. Nevertheless, in actual nontrivial installations, this part typically represents, apart from the cost for peripheral device, roughly half of the overall installation costs. The automation scenario includes all the problems of integrating computers and their peripherals, plus additional issues that have to do with the variety of (electrically and mechanically incompatible) devices and their interaction with the physical environment (including their inaccuracies, tolerances, and unmodeled physical effects such as backlash and friction). The number of variations is enormous so it is often not possible to create reusable solutions. In total, this results in a need for extensive engineering to put a robot to work (Table 54.5). This engineering is what we call system integration.

Carrying out system integration according to current practice is not a scientific problem as such (although how to improve the situation is), but the obstacles it comprises form a barrier to applying advanced sensor-based control for improved flexibility, as

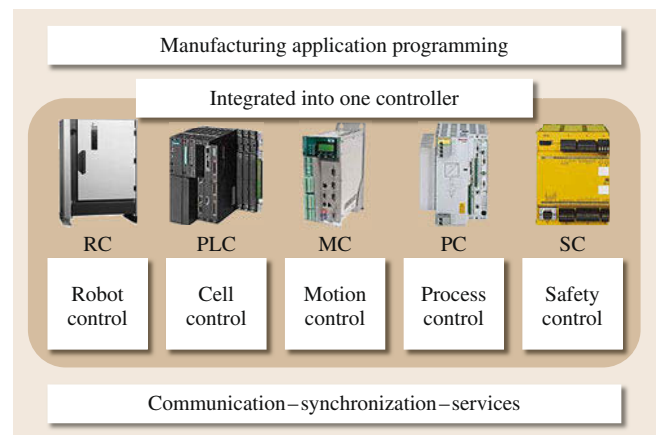

Table 54.5 Stages of system integration, typically carried out in the order listed

Physical	Selecting equipment based on dimensioning for mechanical size, load, and stress
	Mechanical interfacing (locations, adapter plates, etc.)
	Electrical power supply (voltages and currents for robots, effectors, feeders, etc.)
	Connections for analog signals (shielding, scaling, currents, binary levels, etc.)
	Safety design and risk assessment
Communication	Interconnections for single-bit digital I/O
	Byte-wise data communication, including latencies and bit rates
	Transfer of byte sequences
Configuration	Configuration of messages between interacting devices
	Establishment of services
	Tuning for performance and resource utilization
Application	Definition of application-level functions/services
Task	Application programming, using the application-level services

Fig. 54.30 Manufacturing cell with a multicontroller architecture with dedicated controllers (robot motions, production sequences, positioning systems, processes and worker safety). In modern robot controllers, such as the KUKA KR C4, these controllers are replaced by software tasks of a single multifunctional robot controller, thus reducing investment costs on controllers and communication, simplifying engineering, programming and diagnosis, and enhancing process quality and shortening cycle time ►

is needed in small series production. In particular, in future types of applications using external sensing and high-performance feedback control within the workcell, system integration will be an even bigger problem since it includes tuning of the feedback too.

For large series production (e.g. in the automotive industry), the engineering cost of system integration is

less of a problem since its cost per manufactured part is small. On the other hand, the trend toward smaller series

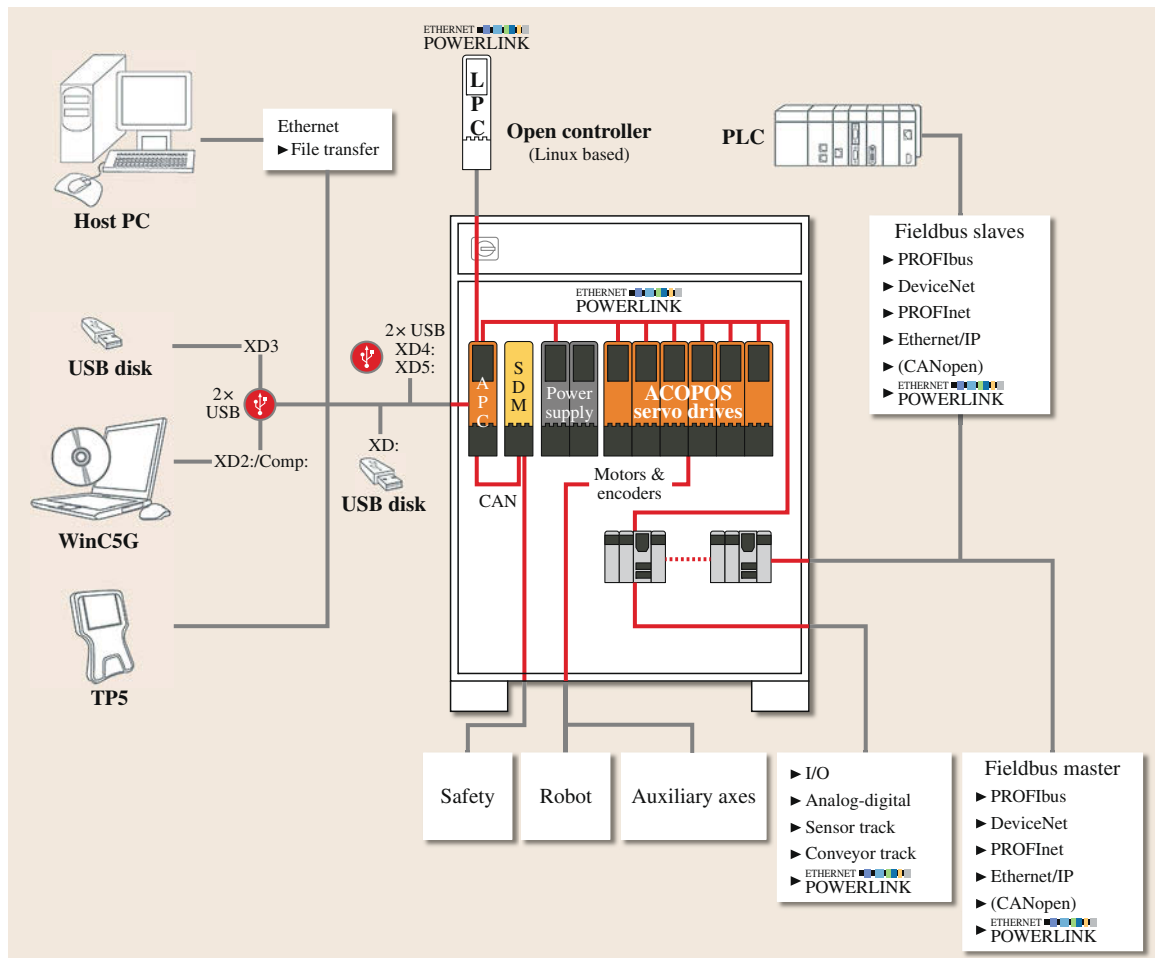

Fig. 54.31 Control modules and interfaces in a typical (but open) robot controller. Several of the named network technologies are based on Ethernet, ranging from normal LAN to different real-time protocols (courtesy of COMAU)

of customized products, or products with many variants that are not kept in stock, calls for high flexibility and short changeover times. Flexibility in this context refers to variable product variants, batch sizes, and process parameters. In particular, this is a problem in small and medium-sized productions, but the trend is similar for larger enterprises as flexibility requirements are continuously on the rise. One may think that simply by using standards for input/output (I/O) and well-defined interfaces, integration should be just a matter of connecting things together and run the system.

Of course, the object-oriented software solution would be to have a gripper class with operations grasp and release. That would be appropriate for a robot simulator in pure software, but for integration of real systems such encapsulation of data (abstract data types) would introduce practical difficulties because:

- Values are explicit and accomplished by external (in this case) hardware, and for testing and debugging we need to access and measure them.
- Online operator interfaces permit direct manipulation of values, including reading of output values.

The use of functions of object methods (so-called setters and getters) would only complicate the picture; maintaining consistency with the external devices would be no simpler.

Already in small installations, the complexity of system integration becomes apparent. So-called vertical integration means integration of low-level devices with a high-level factory control system, whereas integration of peripherals on (for instance) workcell level is called horizontal integration (Fig. 54.30).

Lack of self-descriptive and self-contained data descriptions that are also useful at the real-time level further increases the integration effort since data interfaces/conversions typically have to be manually written. In some cases, as illustrated in Fig. 54.31, there are powerful software tools available for the integration of the robot user level and the engineering level [54.77]. The fully (on all levels) integrated and nonproprietary system such as the recently discussed Industry4.0 or industrial Internet initiatives is still a challenge, particularly for small and medium-sized productions [54.24].

54.8 Outlook and Long-Term Challenges

The widespread use of industrial robots in standard, large-scale production such as the automotive industry, where robots perform repetitive tasks in well-known environments, resulted in the common opinion that industrial robotics is a solved problem. This opinion was underpinned by the robot systems' impressive automatic performance, based on advanced semiautomatic programming and resulting in an unbeatable product quality when compared to manual labor. However, large-scale production comprises only a minor part of the work needed on an industrial scale in any wealthy society, especially considering the number of companies and the variety of applications and processes that could and should be automated for productivity, health and sustainability reasons.

Global prosperity and wealth requires resource-efficient and human-assistive robots. The challenges today are to recognize and overcome the barriers that are currently preventing robots from being more widely used, especially in small and medium-sized manufacturing.

Taking a closer look at the scientific and technological barriers, we find the following challenges:

- *Human-friendly task specification*, including intuitive ways of expressing permitted/normal/expected variations and errors. There are numerous upcoming and promising techniques for user-friendly
- *Intuitive human-robot interaction* The foreseen variations, and the unforeseen variations experienced during robot work, are difficult to manage. When instructing a human, he/she has an extensive and typically implicit knowledge about the work and the involved processes. To teach a robot, it is an issue both how to realize what the robot does not know, and how to convey the missing information efficiently. Furthermore, a person should feel comfortable and familiar with the robot's functionality and operation during all operational modes including maintenance and error recovery. Research and development toward industrial robotics usability and ergonomics for increasing acceptance and operator efficiency has been of surprisingly low activity in the past.
- *Efficient mobile manipulation*. Successful implementations and systems are available for both mobility and for manipulation, but accomplished

human-robot interaction (such as speech, gestures, manual guidance, and so on), but the focus is still on specification of the nominal task rather than the complete task which is capable of handling foreseen deviations from the nominal case (Part G, Robots and Humans). Taking care of these expected deviations can account for up to 80% of the total programming time.

in different systems and using different types of (typically incompatible) platforms. A first step would be to accomplish mobile manipulation at all, combining all degrees of freedom of both the mobile base and arm(s), intelligently exploiting system redundancies to achieve a given task. A second step providing truly dependable autonomous navigation (with adaptive, but predictable understanding of constraints, such as frequent environmental changes and typical shop-floor dynamics, and appropriate sensor-based reactions) dexterous manipulation with multifingered grippers, and robust force/torque interaction with environments (that have unknown stiffness). As a concluding step, all this needs to be done with decent performance using reasonably priced hardware, and with human-robot interfaces according to the previous items.

- *Low-cost components including low-cost actuation.* Actuation of high-performance robots represent about two-third of the overall robot cost, and improved modularity often results in a higher total hardware cost (due to less opportunities for mechatronic optimization). On the other hand, cost-optimized (with respect to certain applications) systems result in more-specialized components and smaller volumes, with higher costs for small series production of those components. Since future robotics and automation solutions might provide the needed cost efficiency for small series customized components, we can interpret this as a boot-straping problem, involving both technical and business aspects. The starting point is probably new core components that can fit into many types of systems and applications, calling for more mechatronics research and synergies with other products.
- *Composition of subsystems.* In most successful fields of engineering, the principle of superposition holds, meaning that problems can be divided into subproblems and that the solutions can then be superimposed (added/combined) onto each other such that the total solution comprises a solution to the overall problem. These principles are of key importance in physics and mathematics, and within engineering some examples are solid-state mechanics, thermal dynamics, civil engineering, and electronics. However, there is no such thing for software, and therefore not for mechatronics (which includes software) or robotics (programmable mechatronics) either. Thus, composition of un-encapsulated subsystems is costly in terms of engineering effort. Even worse, the same applies to encapsulated software modules and subsystems. For efficiency, system interconnections should go directly to known (and hopefully standardized) interfaces, to avoid

the indirections and extra load (weight, maintenance, etc.) of intermediate adapters (applying to both mechanics for end-effector mounting and to software). Interfaces can be agreed upon, but the development of new versions typically maintains backward compatibility (newer devices can be connected to old controller), while including the reuse of devices calls for mechanisms for forward compatibility (automatic upgrade based on meta information of new interfaces) to cover the case that a device is connected to a robot that is not equipped with all the legacy or vendor-specific code.

- *Embodiment of engineering and research results.* Use or deployment of new technical solutions today still starts from scratch, including analysis, understanding, implementation, testing, and so on. This is the same as for many other technical areas, but the exceptional wide variety of technologies involved with robotics and the need for flexibility and upgrading makes it especially important in this field. Embodiment into components is one approach, but knowledge can be applicable to engineering, deployment, and operation, so the representation and the principle of usage are two important issues. Improved methods are less useful if they are overly domain specific or if engineering is experienced to be significantly more complicated. Software is imperative, as well as platform and context dependent, while know-how is more declarative and symbolic. Thus, there is still a long way to go for efficient robotics engineering and reuse of know-how.
- *Open dependable systems.* Systems need to be open to permit extensions by third parties, since there is no way for system providers to foresee all upcoming needs in a variety of new application areas. On the other hand, systems need to be closed such that the correctness of certain functions can be ensured. Extensive modularization in terms of hardware and supervisory software make systems more expensive and less flexible (contrary to the needs of openness). Highly restrictive frameworks and means of programming will not be accepted for widespread use within short-time-to-market development. Most software modules do not come with formal specification, and there is less understanding of such needs. Thus, systems engineering is a key problem.
- *Sustainable manufacturing.* Manufacturing is about transformation of resources into products, and productivity (low cost and high performance) is a must. One aspect of sustainability deals with energy-efficiency of the devices that are used for production. Saving energy can constrain the path planning of an

individual and a whole fleet of robots, and even shift the operation of energy-consuming tasks in periods of the day where energy cost are low. A second aspect of sustainability deals with recycling of scarce resources in terms of materials and noble earths. In most cases, this can be achieved by crushing the product and sorting the materials, but in some cases disassembly and automatic sorting of specific parts are needed. There is, therefore, a need for robots

in recycling and de-manufacturing. Based on future solutions to the above items, this is then a robot application challenge.

An overall issue is how both industry and academia can combine their efforts such that sound business can be combined with scientific research so that future developments overcome the barriers that are formed by the above challenges.

55. Space Robotics

Kazuya Yoshida, Brian Wilcox, Gerd Hirzinger, Roberto Lampariello

In the space community, any unmanned spacecraft can be called a robotic spacecraft. However, *Space Robots* are considered to be more capable devices that can facilitate manipulation, assembling, or servicing functions in orbit as assistants to astronauts, or to extend the areas and abilities of exploration on remote planets as surrogates for human explorers.

In this chapter, a concise digest of the historical overview and technical advances of two distinct types of space robotic systems, orbital robots and surface robots, is provided. In particular, Sect. 55.1 describes orbital robots, and Sect. 55.2 describes surface robots. In Sect. 55.3, the mathematical modeling of the dynamics and control using reference equations are discussed. Finally, advanced topics for future space exploration missions are addressed in Sect. 55.4.

55.1 Historical Developments and Advances of Orbital Robotic Systems

Key issues in space robots and systems are characterized as follows:

Manipulation – Although manipulation is a basic technology in robotics, microgravity in the orbital environment requires special attention to the motion dynamics of manipulator arms and objects being handled. Reaction dynamics that affect the base body, impact dynamics when the robotic hand contacts an object to be handled, and vibration dynamics due to structural flexibility are included in this issue.

Mobility – The ability for locomotion is particularly important in exploration robots (rovers) that travel on the surface of a remote planet. These surfaces are natural and rough, and thus challenging to traverse. Sensing and perception, traction mechanics, and vehicle dynamics, control and navigation; all of these mobile robotics technologies must be demonstrated in a natural untouched environment.

Teleoperation and Autonomy – There is a significant time delay between a robotic system at a work site and a human operator in an operation room on the earth. In earlier orbital robotics demonstrations, the latency was typically 5 s, but can be several tens of minutes, or even hours for planetary missions. Telerobotics technology is therefore an indispensable ingredient in space robotics, and the introduction of autonomy is a reasonable consequence.

Extreme Environments – In addition to the microgravity environment that affects the manipulator dynamics or the natural and rough terrain that affects surface mobility, there are a number of issues related to extreme space environments that are challenging and must be solved in order to enable practical engineering applications. Such issues include extremely high or low temperatures, high vacuum or high pressure, corrosive atmospheres, ionizing radiation, and very fine dust.

The first robotic manipulator arm used in the orbital environment is the shuttle remote manipulator system (SRMS). It was successfully demonstrated in the STS-2 mission in 1981 and was operational until the end of the shuttle era. This success opened a new era of orbital robotics and inspired a number of mission concepts to the research community. One ultimate goal that has been discussed intensively after the early 1980s is the application to the rescue and servicing of malfunctioning spacecraft by a robotic free-flyer or free-flying space robot (e.g., ARAMIS report [55.1],

Fig. 55.1). In later years, manned service missions were conducted for the capture-repair-deploy procedure of malfunctioning satellites (Intelsat 603 by STS-49, for example) and for the maintenance of the Hubble space telescope (STS-61, 82, 103, and 109). For all of the examples, the Space Shuttle, a manned spacecraft with dedicated maneuverability, was used. However, unmanned servicing missions have not yet become operational. Although there were several demonstration flights, such as ETS-VII and Orbital Express (to be elaborated later), the practical technologies for unmanned satellite servicing missions await solutions to future challenges.

55.1.1 Robotic Arms for Assistance of Human Space Flight

Space Shuttle Remote Manipulator System

Onboard the space shuttle, the SRMS, or Canadarm, is a mechanical arm that maneuvers a payload from the payload bay of the space shuttle orbiter to its deployment position and then releases it [55.2]. It can also grapple a free-flying payload, maneuver it to the payload bay of the orbiter, and berth it back into the orbiter. The SRMS was first used on the second Space Shuttle mission STS-2, launched in 1981. Since then, it was used more than 100 times during space shuttle flight missions, performing such payload deployment or berthing as well as assisting human extra vehicular activities (EVAs). Servicing and maintenance missions to the Hubble space telescope and construction tasks of the International Space Station (ISS) have also been

Fig. 55.1 A conceptual design of telerobotic servicer (after [55.1])

Fig. 55.2 Space Shuttle remote manipulator system (SRMS) (after [55.2])

successfully carried out by the cooperative use of the SRMS with human EVAs.

As depicted in Fig. 55.2, the SRMS arm was 15 m long and had 6-degrees of freedom (DOF), comprising shoulder yaw and pitch joints, an elbow pitch joint, and wrist pitch, yaw, and roll joints. Attached to the end of the arm was a special gripper system called the standard end effector (SEE), which was designed to grapple a pole-like fixture (GF) attached to the payload.

By attaching a foothold at the end point, the arm could serve as a mobile platform for an astronaut's EVAs (Fig. 55.3).

After the Space Shuttle COLUMBIA accident during STS-107, NASA outfitted the SRMS with the orbiter boom sensor system – a boom containing instruments to inspect the exterior of the shuttle for damage to the thermal protection system [55.3].

ISS Mounted Manipulator Systems

The ISS is the largest international technology project, with 15 countries making significant cooperative contributions. The ISS is an *outpost* of human presence in space, as well as a *flying laboratory* with substantial facilities for science and engineering research. In order

Fig. 55.3 Space shuttle remote manipulator system (SRMS) used as a platform for an astronaut's extra vehicular activity in the shuttle cargo bay

to facilitate various activities on the station, there are several robotic systems, some of which are already operational, while others are ready for launch.

The space station remote manipulator system (SSRMS), or Canadarm 2 (Fig. 55.4), was the next generation of SRMS for use on the ISS [55.4]. Launched in 2001 during STS-100 (ISS assembly flight 6A), the SSRMS has played a key role in the construction and maintenance of the ISS both by assisting astronauts during EVAs and using the SRMS on the Shuttle to hand over a payload from a Shuttle to the SSRMS. The arm is 17.6 m long when fully extended and has 7-DOF. Latching end effectors, through which power, data, and video can be transmitted to and from the arm, are attached to both ends. The SSRMS is self-relocatable using an inch-worm like movement with alternate grappling of power data grapple fixtures (PDGFs), which are installed over the station's exterior surfaces to provide the power, data, and video, as well as a foothold.

As another mobility aid for the SSRMS to cover wider areas of ISS, mobile base system (MBS) was added in 2002 by STS-111 (ISS assembly flight UF-2). The MBS provides lateral mobility as it traverses the rails on the main trusses [55.5].

The special purpose dexterous manipulator (SPDM), or Dextre, which is attached at the end of the SSRMS, is a capable mini-arm system to facilitate the delicate assembly tasks currently handled by astronauts during EVAs. The SPDM is a dual arm manipulator system, where each manipulator (with 3 m length) has 7-DOF and is mounted on a one degree-of-freedom

body joint. Each arm has a special tool mechanism dedicated to the handling of standardized orbital replacement units (ORUs). The arms are teleoperated from a Robotic WorkStation (RWS) inside the space station [55.6].

The European Space Agency (ESA) will also provide a robotic manipulator system for the ISS, the European robotic arm (ERA), and will be used mainly to work on the Russian segments of the station [55.7]. The arm is 11.3 m long and has 7-DOF. The basic configuration and functionality are similar to SSRMS [55.8].

In Japan, the Japanese experiment module remote manipulator system (JEMRMS), as shown in Fig. 55.5, was developed by the Japan Space Exploration Agency (JAXA) [55.9–11]. The arm was launched with the STS-124 Mission in 2008 and is now operative on the Japanese module of the ISS. JEMRMS comprises two components: the main arm, a 9.9 m long, six-degree-of-freedom arm, and the small fine arm, a 1.9 m long, six-degree-of-freedom arm.

Unlike the SSRMS or the ERA, the main arm does not have self-relocation capability, but is fitted with a small fine arm, with which JEMRMS can form a serial 12-degree-of-freedom macro-micro manipulator system. After installation, the arm is used to handle and relocate the components for the experiments and observations on the exposed facility.

55.1.2 Future-Oriented Space Robot Experiments

ROTEX

The Robot Technology Experiment (ROTEX) developed by the German Aerospace Agency (DLR), is one of the important milestones of robotics technology in space [55.12], as it demonstrated the first (remote) ground control of a space robot with of up to 6 s round-trip signal delay using geostationary relay satellites. A multisensory robotic arm was flown on Space Shuttle COLUMBIA (STS-55) in 1993. Although the robot worked inside a work cell on the shuttle, several key technologies, such as a multisensory gripper, teleoperation from the ground and by the astronauts, shared autonomy, and time-delay compensation by use of a predictive graphic display were successfully tested (Fig. 55.6 and VIDEO 330).

Presumably the most spectacular experiment in ROTEX was the fully automatic grasping of a small free-floating cube with flattened edges by the ground computers who evaluated the stereo images from the robot gripper, estimated the motion, predicted for the above-mentioned 6 s and sent up the commands for grasping (VIDEO 331).

Fig. 55.4 Space station remote manipulator system (SSRMS) (after [55.4])

ETS-VII

Engineering Test Satellite VII (ETS-VII), shown in Fig. 55.7, is another milestone in the development of robotics technology in space, particularly in the area of satellite servicing. ETS-VII was an unmanned spacecraft developed and launched by the National Space Development Agency of Japan (NASDA, currently JAXA) in November 1997. A number of experiments were successfully conducted using a 2 m long, six-degree-of-freedom manipulator arm mounted on its carrier satellite.

The mission objective of ETS-VII was to test free-flying robotics technology and to demonstrate its utility in unmanned orbital operation and servicing tasks. The mission consisted of two subtasks: autonomous rendezvous/docking (RVD) and a number of robot experiments (RBT). The robot experiments included: (1) teleoperation from the ground with a large time delay; (2) robotic servicing task demonstrations such as ORU exchange and deployment of a space structure; (3) dynamically coordinated control between the manipulator reaction and the satellite attitude response; and (4) capture and berthing of a cooperative target satellite [55.13].

The communication time delay due to radio propagation (speed-of-light) is relatively small, for example 0.25 s for a round trip to geostationary Earth orbit (GEO). However, to have a global coverage of communication in low Earth orbit (LEO) operations, the signals are transmitted via multiple nodes including data relay satellites located at GEO and ground stations. This makes the transmission distance longer, and even more additional delays are added at each node. As a result, the cumulative delay becomes some seconds, actually 5–7 s in case of ETS-VII mission, more or less the same as in the ROTEX experiment. However, it is important to state that these delays have been unnecessarily long as the optimal communication infrastructure was (and is still) missing. Figure 55.8 shows that for a low orbit robot satellite (with typically 1.5 h orbital period) half of the orbit (i.e., around 45 min) would have communication from the ground station via one relay satellite yielding approximately 600 ms round trip delay (including computational delays). For a robot in geostationary orbit having permanent communication to the ground station, the round trip delay would be only 300 ms.

In ETS-VII, opportunities for academic experiments were also opened to Japanese universities and European institutions (e.g., DLR and ESA), and important flight data were obtained that validate the concepts and theories for free-flying space robots [55.14, 15]. As an example, DLR performed experiments aiming at demonstrating robot control methods for performing ORU exchange tasks (see for example  VIDEO 332)

Fig. 55.5 (a) Japan Experiment Module (JEM) on the ISS and (b) the JEMRMS manipulator system

and dedicated satellite attitude control via *swimming* or *waiving* motions of the robot arm.

Ranger

Ranger is a teleoperated space robot being developed at the University of Maryland, Space Systems Laboratory [55.16]. Ranger consists of two seven-degree-of-freedom manipulators with interchangeable end effectors to perform such tasks as changeout of orbital replacement units (ORUs) in orbit. Also discussed was the changeout of the electronics controller unit (ECU) of the Hubble space telescope, which previously required human EVA. A number of tests and demon-

Fig. 55.6 ROTEX manipulator arm onboard the Spacelab D2 mission, the first remotely controlled space robot

Fig. 55.7 Japanese Engineering Test Satellite ETS-VII

strations for servicing missions have been conducted at the University of Maryland Neutral Buoyancy Facility (Fig. 55.9). Originally designed for a free-flying flight experiment, Ranger had been redesigned for a shuttle flight experiment, but ultimately was not manifested on a shuttle flight.

Orbital Express

The Orbital Express Space Operations Architecture program is a DARPA program developed to validate the technical feasibility of robotic on-orbit refueling and reconfiguration of satellites, as well as autonomous rendezvous, docking, and manipulator berthing [55.17]. The system consists of the autonomous space transport robotic operations (ASTRO) vehicle, developed by Boeing Integrated Defense Systems, and a prototype modular next-generation serviceable satellite, NextSat, developed by Ball Aerospace. The ASTRO vehicle is

Fig. 55.8 Minimal *Roundtrip* signal propagation delay to robots in LEO is around 0.6 s, to robots in GEO around 0.3 s

Fig. 55.9 Neutral buoyancy test of the Ranger telerobotic shuttle experiment

equipped with a robotic arm to perform satellite capture and ORU exchange operations (Fig. 55.10).

After its launch in March 2007, various mission scenarios were conducted. These scenarios include (1) visual inspection, fuel transfer, and ORU exchange on NextSat using ASTRO's manipulator arm when both spacecrafts are connected, (2) separation of NextSat from ASTRO, orbital maneuvers by ASTRO, and fly-around, rendezvous, and docking with NextSat, and (3) capture of NextSat using ASTRO's manipulator arm.

These scenarios were successfully completed by July 2007, with ASTRO's onboard autonomy using on-board cameras and advanced video guidance system.

Fig. 55.10 Orbital express flight mission configuration

ROKVISS and Delayed Teleoperation

As a precursor demonstration of the planned German Orbital Servicing demonstration mission DEOS (see below), the German Aerospace Agency (DLR) has developed and flown a 0.5 m long, two-degree-of-freedom manipulator arm with a dedicated test bench, called robotic components verification on the ISS (ROKVISS) (Fig. 55.11) [55.18].

Using the 7–8 min contact window of the ISS over-flight through a dedicated real-time space link, resulting in a roundtrip delay as small as 20 ms, this was the first high-fidelity telepresence system in the history of space flight that allowed force feedback teleoperation. A large amount of data documenting the evolution of electrical and mechanical properties of the robot (such as sensor accuracy, friction, and motor parameters) has been collected during the six year mission.

ROKVISS was launched by an unmanned Russian progress transport vehicle in 2004 and installed on the outer platform of the Russian segment of the station in early 2005 (VIDEO 333).

After six years, the system was still fully functional, even though it had undergone only low-cost qualification, i.e., most of the electronic components were off-the-shelf and the system as a whole had been qualified by radiation, vibration, and temperature tests. The long-time verification of these joints for outer space has been a second main goal of ROKVISS (VIDEO 334). Toward the end of the mission, ROKVISS was teleoperated from the private home of the project leader using standard internet communication to DLR's professional ground station. Round-trip delay went then up to around 400 ms still allowing telepresence with force-reflection. At the end of 2011, ROKVISS was brought back to Earth for completion of verification and validation tests (VIDEO 336).

Fig. 55.11 ROKVISS – 6 years on ISS

Although the numbers of joints was small, challenging experiments of telepresence were conducted, in which human operators from ground teleoperated the arm using a force feedback joystick and stereo vision images. The ROKVISS arm, on the other hand, was equipped with joint torque sensors, allowing full impedance control and advanced bilateral control techniques. The secondary goal of the experiment was the space qualification of the joint drives, which are the key components of DLR's torque-controlled lightweight robots [55.19].

No electrical or mechanical damages were visible, and the main observation was that joint friction had nearly doubled in vacuum on ISS, but went back to its original value when the arm was back on earth again. In the framework of ROKVISS and the accompanying investigations, important basic clarifications of the general telepresence potentials and prerequisites could be achieved.

Already in the early days of space telerobotics as pushed forward by JPL, there have been estimates that humans might be able to master signal delays of up to 1 s in the visual system (i.e., looking at delayed images) and up to 500 ms with the haptic system from the proprioceptive point of view.

The interesting, fairly recent result is here [55.20, 21], where feasibility of force-reflecting teleoperation with communication delays as high as 650 ms has been proven. By using the so-called time domain passivity control approach, the mechanical energy of the system is observed and controlled in real time, such that the system is passive for any given communication channel characteristics, including varying time delays and packet loss. These results have been verified with a unique telepresence experiment, where two torque-controlled light weight arms located in Oberpfaffenhofen (Germany) were connected through a real relayed communication link that used the geostationary satellite ARTEMIS, ground station communication an-

Fig. 55.12 Force-reflecting telepresence demos at DLR

tennas located in Garching (Germany) and a data mirror in Redu (Belgium) [55.22].

Recently, telepresence experiments with a fairly complex multidegree-of-freedom (DOF) system have been performed [55.23]. The system consisted of the DLR's *Space JUSTIN* humanoid robot and a human-machine interface based on two torque-controlled light weight arms as a force reflecting hand controller (haptic device) (Fig. 55.12 and [VIDEO 337](#)). Complex tasks that required with high levels of dexterity, such (un)screwing with a screwdriver and soldering, were performed with time delays up to 500 ms ([VIDEO 338](#)).

It is therefore concluded that teleoperation with force feedback is possible over the whole earth orbit.

The DEOS Demonstration Project

The German space robotics-demonstration mission DEOS, based on the [ROKVISS](#)-joint torque-controlled arm technology, aims at the demonstration of the maturity and availability of key technologies as needed for an orbit servicing. DEOS is comprised of two satel-

Fig. 55.13 DEOS – orbital servicing experiment with client (left) and servicer (right)

lites, servicer and client (Fig. 55.13). Its main goal is to find, approach, and capture an uncontrolled and uncooperative satellite in LEO ([VIDEO 339](#)). After successful capturing some typical repair and maintenance tasks are planned to be demonstrated before the servicing satellite enters the atmosphere for a controlled descent together with the captured satellite. Project developments are currently being pursued to advance the technological readiness level, in view of future missions. Developments also include adaptations to Active Debris Removal missions in study, such as e.Deorbit (ESA), for the deorbiting of the ENVISAT satellite.

Robonaut and JUSTIN

Humanoid (human-like) robots have been developed to conduct human-compatible dexterous tasks. NASA's Robonaut and DLR's JUSTIN are such representative examples. These robots are elaborated in Sect. 55.4.2.

55.2 Historical Developments and Advances of Surface Robotic Systems

The research on surface exploration rovers began in the mid-1960s, with an initiative (that never flew) for an unmanned rover for the Surveyor lunar landers and a manned rover (Moon buggy) for the human landers in the United States. In the same period, research and development began for a teleoperated rover named Lunokhod in the Soviet Union. Both the Apollo-manned rover and the Lunokhod-unmanned rover were successfully demonstrated in the early 1970s on Moon [55.24]. In the 1990s, the exploration target had expanded to Mars, and in 1997, the Mars Pathfinder Mission successfully deployed a microrover named Sojourner that safely traversed the rocky field adjacent to the landing site by autonomously avoiding obstacles [55.25, 26]. Following this success, today,

autonomous robotic vehicles are considered indispensable technology for planetary exploration. The twin Mars Exploration Rovers, Spirit and Opportunity, were launched in 2003, and have had remarkable success in terms of remaining operational in the harsh environment of Mars for over three years. Each has traveled more than 5000 m and has made significant scientific discoveries using on-board instruments [55.27, 28].

55.2.1 Teleoperated Rovers

The first remotely operated robotic space surface vehicle was Lunokhod (Fig. 55.14) [55.24]. Lunokhod 1 landed on the Moon on November 17, 1970 as a payload on the lander Luna-17, and Lunokhod 2 landed on the

Fig. 55.14 Lunokhod

Moon on January 16, 1973. Both were 8-wheeled skid-steered vehicles having a mass of about 840 kg, where almost all the components were in a pressurized *bathub* thermal enclosure with a lid that closed over the tub to allow it to survive the deep cold (≈ 100 K) of the long lunar nights using only the heat emitted by small pellets of radioisotope. On the inside of the lid were solar arrays which recharged batteries during the day as required to maintain operation of the vehicle. Lunokhod 1 operated for 322 Earth days, traversing over 10.5 km during that period, and returned over 20 000 TV images, 200 high-resolution panoramas, and the results of more than 500 soil penetrometer tests and 25 soil analyses using its x-ray fluorescence spectrometer. Lunokhod 2 operated for about 4 months, having traversed more than 37 km, with the mission officially terminated on June 4, 1973. It has been reported that Lunokhod 2 was lost prematurely when it began sliding down a crater slope and hasty commands were sent in response which ultimately caused end-of-mission.

Each of the eight wheels on the Lunokhod vehicles were 0.51 m in diameter and 0.2 m wide, giving an effective ground pressure of less than 5 kPa based on an assumed sinkage of 3 cm. Each wheel had a brush-type DC motor, a planetary gear reduction, a brake, and a disengagement mechanism allowing it to free-wheel

in the event of some problem with the motor or gears. The mobility commands to the vehicle included two speeds forward or backward, braking, and turning to the right or the left either while moving or in place.

The vehicles had both gyroscope and accelerometer-based tilt sensors which could automatically stop the vehicle in the event of excessive tilt of the chassis. Typical mobility commands specified a time duration over which the motors would run, and then stop. Precision turning commands specified the angle through which the vehicle should turn. These commands were terminated when the specified turn angle had been reached according to the heading gyroscope. Odometry was determined by a ninth *small wheel* which was unpowered and lightly loaded and used only to determine over-the-ground distance. There was an on-board current overload system, and motor currents, pitch and roll measurements, distance traversed, and many component temperatures were telemetered to the ground operators.

The Lunokhod crew consisted of a driver, a navigator, a lead engineer, an operator for steering the *pencil-beam* communication antenna, and a crew commander. The driver viewed a monoscopic television image from the vehicle, and gave the appropriate commands (*turn*, *proceed*, *stop*, or *back up*) along with their associated parametric value in terms of duration or angle. The navigator viewed displays of telemetry from the vehicles' *course gyroscope*, *gyrovertical sensor*, and odometer, and was responsible for calculating the trajectory of the vehicle and laying out the route to be followed. Thus, the driver was responsible for vehicle stability about its center of mass and the navigator was responsible for the trajectory of that center of mass. The lead engineer (assisted by many specialists as required), was responsible for assessing the health of the on-board systems. The lead engineer provided both routine updates on energy supply, thermal conditions, etc., as well as possible emergency alerts such as extreme motor currents or chassis tilt. The pencil-beam antenna operator oversaw the functioning of an independent ground-based closed-loop control system that servoed the antenna to always point at Earth, independent of the vehicle motion. The crew commander supervised the implementation and execution of the overall plan, gave any detailed commands for making actual contact with the surface (e.g., by the penetrometer) and also could override any command to the vehicle as he viewed the same information as the driver.

The entire driving system was tested extensively prior to the Lunokhod 1 mission at a *lunodrome* having simulated lunar terrain which proved to be more challenging than that actually encountered during the Lunokhod 1 mission. Despite this, the operators of Lunokhod 1 said they *encountered a dangerous situ-*

ation (unforeseen entrance into a crater, rolling onto a rock, etc.) slightly more often than once per kilometer. This was attributed to inadequate driving experience, the modest quality of the television images, and the poor illumination conditions on the Moon. The driving direction was often selected primarily to give the best images; even so, the operators reported *fictitious dangers* caused by varying illumination conditions. In the first three months (lunar days) of operation, the vehicle traversed 5224 m in 49 h of driving using 1695 driving commands, including about 500 turns. Sixteen signals were sent for protection against excessive tilt during that time; approximately 140 craters were traversed at maximum slope angles of 30°.

With the approximately 2.6 s speed-of-light delay, the operators stated that *control experience confirmed the desirability of movement in a starting-stopping regime with mandatory stopping each few meters*. The soil properties were found to *differ substantially even in terrain sectors not very distant from one another*. The soil penetrometer determined that the upper layer of regolith varied from a stiffest where the penetrometer required about 16 kg (Earth weight) of force to penetrate about 26 mm, to a weakest measurement where only 3 kg of Earth weight caused a penetration of about 39 mm. The cone penetrometer had a base diameter of 50 mm and a cone height of 44 mm. Thus the upper layer of regolith had a rate of increase of loadbearing strength ranging from about 400 kPa m⁻¹ for the weakest soil to about 3 MPa m⁻¹ for the stiffest soil. Crater walls and the immediate ejecta blanket around craters generally exhibited the weakest soil. Below 5–10 cm of penetration depth, the regolith generally became rapidly stiffer. The mean value of wheel slippage for the first three lunar days was about 10%. On horizontal terrain, the slippage ranged from zero to 15% depending on the surface irregularities and ground inhomogeneity. On crater slopes, the slip increased to 20–30%. The specific resistance of the Lunokhod wheels was generally in the range of 0.05–0.25, while the specific free traction (the ratio of traction to weight) was in the range of 0.2–0.41. The crater distribution in the area explored by Lunokhod 1 was found to be closely approximated by the formula $N(D) = AD^{-\delta}$, where $N(D)$ is the number of craters larger than diameter D meters per hectare of lunar surface, A is a scale factor found to be about 250, and δ is the distribution exponent, found to be about 1.4 [55.24].

55.2.2 Autonomous Rovers

In the mid-1960s, research began on a lunar rover at the US Jet Propulsion Laboratory (JPL) in Pasadena, California, when it was proposed to put a small rover on

the Surveyor lunar landers. These landers were led by JPL (based on a system-level contract to Hughes), and were designed to land softly on the Moon to establish the safety of such landing prior to the Apollo landers with humans aboard. At the time it was speculated (notably by T. Gold) that the Moon might be covered in a thick layer of soft dust that would *swallow* any lander. In 1963, JPL issued a contract to build a small rover concept prototype in support of the Surveyor program to the General Motors Defense Research Laboratories in Goleta, California. That GM facility had recently hired *Bekker*, who was considered *the father of off-road locomotion*, having written several seminal textbooks on the subject, and having introduced many of the key concepts relating soil properties to off-road vehicle performance that are still used today [55.29, 30] (Sect. 55.3.12).

Bekker and his team proposed an articulated 6-wheeled vehicle based on a novel 3 cab configuration with an axial spring-steel suspension. This vehicle exhibited remarkable mobility, being able to climb vertical steps up to 3 wheel radii high, and crossing crevasses 3 wheel radii wide. Notable people working with Bekker were Farenc Pavlics, who went on to lead the development of the mobility system for the Apollo lunar rover (under contract from Boeing), and Fred Jindra, who developed the underlying equations describing the mobility of the 6-wheeled articulated vehicle that were later used by Don Bickler in conceiving of the *rocker bogie* chassis used on Sojourner and the Mars Exploration Rovers. Bekker and his team proposed the 6 wheeled articulated vehicle after experimenting with many types of vehicles, including multitracked vehicles, screw-type vehicles (for fine powdered terrain), and others. The 6-wheeled vehicle demonstrated in scale-model testing superior performance in both soft and rocky terrain.

They built and delivered two vehicles that were about 2 m long with approximately 0.5 m wheel diameters. Those vehicles were used in testing throughout the 1960s and early 1970s to conduct simulated operations to determine how such vehicles could actually be used on the Moon. One key issue was that the speed-of-light round trip from the Moon (about 3 s) precluded direct *driving* of the vehicle. Perhaps most annoying was the fact that, during vehicle motion, the highly directional radio antenna used to communicate with Earth would lose its pointing, and so communications would briefly be lost. This meant that operators driving the rover would be confronted with a series of still images, instead of a stream of moving images. It was quickly realized that much of an operator's *situation awareness* and depth perception needed to drive a vehicle with a monocular camera comes from motion. It

was very difficult to drive from frozen monocular images. A crude form of stereo was incorporated where the camera mast was raised and lowered slightly and the operator could switch back and forth between the two views.

Following the successful landing of several of the Surveyor spacecraft, and the discovery that all landing sites seemed to have relatively firm soil, it was concluded that the Surveyor lunar rover was not needed. As a result, the prototype was used for research into the early 1970s, and subsequently restored for use again in research in the 1980s, becoming the first vehicle to be outfitted with *waypoint navigation* of the sort later used on the Sojourner and MER missions.

About the time Viking was conceived and developed, JPL began the 1984 Mars rover effort. (1984 was an energetically favorable launch opportunity from Earth to Mars, and the next likely major mission opportunity after Viking.) Two testbed vehicles were developed, a *software* prototype and a *hardware* prototype. The software prototype had a *Stanford* arm, designed by Vic Scheinman (who went on to design the Unimation PUMA arm and many other famous early robotic devices). This was the only *1.5-scale* Stanford arm ever built. *Lewis* and *Bejczy* became well-known in robotics for solving the kinematics of this arm, one of is not the first full kinematics ever done in robotics up to that time, e.g., [55.31]. A stereo pan-tilt head was implemented and equipped with the first solid-state cameras to become available. A number of very important works were published in the 1977 International Joint Conference on artificial intelligence, e.g., [55.32, 33]. The first *hand-eye-locomotion* coordination was done with this vehicle, where a rock was designated in a stereo image, and the vehicle maneuvered autonomously to a point where the arm could reach out and pick up the rock. One of the first demonstrations of *pin in hole* insertion and other *dexterous* manipulations were also done with this system in the 1970s.

The *hardware* prototype was built using elastic *loop wheels* made by Lockheed [55.34]. The vehicle was battery powered and controlled via a handheld RC unit of the type used by hobbyists.

In late 1982, JPL had a contract with the US Army to study the use of robotic vehicles in support of the US Army. During this study, Brian Wilcox at JPL proposed a technique to reduce the need for a real-time video link or high-bandwidth communication channel between the vehicle and the operator. This technique (which became known as computer-aided remote driving, or *CARD*) [55.35] required the transmission of a single stereo image from the vehicle to the operator, so the operator could designate waypoints in that image using a *3-D* cursor. By use of a single stereo image in-

stead of a continuous stream of monocular images, the amount of information that needed to be transmitted by the vehicle was reduced by orders of magnitude. JPL first demonstrated *CARD* on the resurrected surveyor lunar rover vehicle (*SLRV*, which had been painted baby-blue and so became known as the *Blue Rover*, Fig. 55.15a), and later on a modified Humvee. During field tests in the Mojave desert in 1988, *CARD* was demonstrated on the Humvee with path designations of 100 m per stereo image, and with time-to-designate each path of only a few seconds.

As the *CARD* work was ongoing, an internally funded effort at JPL demonstrated a concept called *semiautonomous navigation* (*SAN*). This concept involved humans on Earth designating *global* paths using maps of the sort that could be developed from orbiter imagery, and then having the vehicle autonomously refine and execute a *local* path that avoids hazards. The moderate success of that effort led to a NASA funded effort, leading to the development of a new vehicle, called Robby (Fig. 55.15b). Robby was a larger vehicle that could support the on-board computing and power

Fig. 55.15a,b Six-wheel articulated body rovers developed by JPL (a) *SLRV* and (b) Robby

needed for untethered operation. (The [SLRV](#) had been tethered to a VAX 11/750 minicomputer over a 1500 foot tether during arroyo field testing of [CARD](#).) For the first time (in 1990), an autonomous vehicle had made a traverse through an obstacle field that was faster than a rover could have done on Mars using human path designation done on Earth.

However, Robby had a severe *public relations* problem – it was perceived as too large. Of course, none of the computers or power systems had been miniaturized or lightweighted – it was composed entirely of the lowest-cost components that could do the job. However, because it was the size of a large automobile, observers and NASA management got the impression that future rovers would be car-sized or even truck-sized vehicles. This was compounded by the Mars rover sample return ([MRSR](#)) study done by [JPL](#) in the late-1980s which suggested a mass for the rover of 882 kg. An independent study of the [MRSR](#) study by Science Applications International, Inc. (SAIC) estimated the overall cost at \$13B. When word of this *outrageous* price tag filtered around NASA Headquarters and into the Congressional Staff, [MRSR](#) was summarily killed. Robby died along with it. At about the same time, NASA funded Carnegie Mellon University to develop *Ambler* (Fig. 55.16), a large walking robot that was able to autonomously choose safe footfall locations, also as a testbed Mars Rover [55.36, 37]. *Ambler* had a similar public-relations problem, being about the same mass as Robby, that the NASA management community was very skeptical that such large systems could affordably be flown to Mars. Both Robby and *Ambler* had all-on-board power and computing systems, which at that time were not sufficiently miniaturized to make autonomous rovers credible for actual flight missions. *Moore's law*

Fig. 55.16 Ambler

was not only causing the computing technology to become miniaturized at a high rate, but also the energy required per computing instruction was dropping rapidly. This meant that early systems devoted most of their power to computing rather than to motive power. Later systems, such as the Mars exploration rovers, have a more nearly equal balance between power for mobility and power for computation. Future systems will presumably devote the majority of their power to mobility as opposed to computation.

Soon thereafter, the Mars Environmental Survey ([MESUR](#)) mission set was proposed, as a lower cost alternative to a sample return mission. The [MESUR](#) Pathfinder mission was proposed as a first test of what was envisioned as a network of 16–20 surface stations to provide global coverage of Mars. A small rover was proposed to the Mars Science Working group [55.38, 39]. A very short-term development effort culminated in a demonstration in July 1992 of a ≈ 4 kg rover that could move to directed points on the surface nearby a lander using stereo designation of waypoints in a 3-D display of frozen images taken from a lander mast camera pair (Fig. 55.17). This demonstration was sufficiently successful that a similar rover was manifested for the Mars Pathfinder mission. The Pathfinder rover (Fig. 55.18) was later named Sojourner, and became the first autonomous vehicle to traverse the surface of another planet, using a hazard detection and avoidance system to move safely between waypoints through a rockfield [55.25, 26]. The hazard detection system avoided obstacles, and also was used to position the vehicle accurately in front of rocks. Sojourner operated successfully for 83 Mars days (until the failure of the lander, which was acting as a communications relay between the rover and Earth). Sojourner examined approximately a dozen rock and soil samples with its Alpha-Proton-x-ray spectrometer, which gives the elemental composition of the rocks and soil. The success of Sojourner led directly to the decision to build the twin Mars exploration rovers launched in 2003. Both Sojourner and the subsequent Mars exploration rovers *Spirit* and *Opportunity*, and the Mars Science Laboratory *Curiosity*, use waypoint designation in stereo images by the human operator together with autonomous hazard detection and avoidance to keep the rovers safe if they should wander off the designated path.

During the 1992–1993 summer season in Antarctica, the Dante I robot, built by Carnegie-Mellon University and funded by NASA, attempted to rappel into the caldera of the active volcano Mt. Erebus. Dante was a walking robot, and was the first serious attempt to make a robot rappel down a grade that was too steep to traverse using purely frictional contact. Unfortunately, the extreme cold (even in the summer) compounded

Fig. 55.17 Rocky 4

Fig. 55.18 The Pathfinder rover, Sojourner

by human error caused a kink in the fiber-optic umbilical to snag going through an eyelet, breaking the high-bandwidth fiber communications on which the system depended. The fiber could not be repaired in the field, and so the mission was aborted. Undaunted, in the summer of 1994, Dante II (Fig. 55.19) made a successful rappel into the caldera of Mt. Spur in Alaska, exploring the active vents on the crater floor in a way that would be unsafe in the extreme if done with human explorers. The Dante robot series demonstrated that rappelling, especially when combined with legged locomotion, allows robots to conduct exploration to extremely hazardous sites in ways that humans cannot.

In 1984, NASA started the Telerobotics Research program [55.40, 41]. This program demonstrated various aspects of on-orbit assembly, maintenance, and servicing. Some highlights of this activity were the automated tracking and grappling of a free-spinning satellite (suspended with a counterweight and gimbal

Fig. 55.19 Dante II at Mt. Spur in Alaska

for realistic reactions under external forces), connection of a flight-like fluid coupler, and many *busy box* functions such as door opening, threaded fastener mating and demating, use of power tools, dual-arm manipulation of a simulated hatch cover and flexible thermal blanket, etc., by various control approaches ranging from force-reflecting teleoperation to fully autonomous sequences. This activity ended in about 1990.

55.2.3 Research Systems

There have been many mobile robots built by government, university, and industrial groups whose objective was to develop new technologies for planetary surface exploration, or to excite students or young engineers about the possibilities in that area. Carnegie Mellon University developed the Ambler, Dante, Nomad, Hyperion, Zoe, and Icebreaker robot series. The Jet Propulsion Laboratory (JPL), Draper Labs, MIT, Sandia National Lab, and Martin-Marietta (later Lockheed-Martin) each built more than one planetary surface robot testbed. The Marsokhod chassis built by VNII Transmach of St. Petersburg, Russia was used by research groups there and also in Toulouse (LAAS and CNRS) [55.42, 43] as well as the NASA Ames Research Center and McDonnell Douglas Corporation (later part of the Boeing Company) in the US.

These research platforms have been used for two basic avenues of research. One avenue is to perfect safe driving techniques on planetary surfaces, despite the speed-of-light latencies inherent in robotic exploration of the planets. This includes the waypoint navigation technology developed at JPL in the 1980s, where frozen stereo images are used to plan a possibly lengthy series of waypoints or activity sites, and then executed with various sorts of reflexive hazard avoidance or safing techniques, such as used on the Sojourner rover on Mars in 1997. The other is to develop higher level autonomy for improved science data return or mission robustness. Technologies in this latter category include mission planners that attempt to optimize routes and activity sequences based on time, limits to peak power, total energy, expected temperature, illumination angles, availability of communications, and others.

Fig. 55.20 The Mars exploration rovers, Spirit and Opportunity, with a manipulator arm in front

Fig. 55.21 Rocky 7

Automated classification of possible science targets based on clustering of spectral data, figure-ground segmentation of rocks, and other approaches have been attempted with some success. At the time of this writing, some of these technologies have been uploaded to the twin Mars exploration rovers *Spirit* and *Opportunity* (Fig. 55.20) [55.27], including automated detection of temporary events of scientific interest such as dust-devils and clouds [55.44]. The Spirit rover was lost when it broke through a surface crust into a small crater filled with fine dust in late 2009, with attempts to free it continuing until mid 2010. The Mars Science Laboratory *Curiosity* was landed in August 2012 and seeks to explore Mt. Sharpe in the center of Gale Crater.

The ESA with a number of contractors, e.g., ASI and DLR has been working for several years on a 6-wheeled Mars rover ExoMars that is supposed to be flown after 2018 as well as on a *next lunar lander* NLL Rover, but it is not finally clear, when and in which configuration the mission might be realized.

55.2.4 Sensing and Perception

In the 1980s, most planetary rover sensing research was based on laser ranging or stereo vision. Stereo vision was too computationally intensive for early low-power, radiation-hard processors, so the Sojourner Mars rover used a simple form of laser ranging to determine which areas were safe to traverse. Between the launch of Sojourner (1996) and the Mars exploration rovers (2003) sufficient progress had been made in radiation-hardened flight processors that stereo vision was used for hazard detection on MER [55.45], mostly in experiments conducted with the Rocky-7 rover (Fig. 55.21). This allowed much larger numbers of range points to be incorporated into the hazard-detection algorithm (thousands of points, instead of the 20 discrete range points used by Sojourner). Perception of hazards on Sojourner was based on simple computations of average slope and roughness over the 4×5 array of range measurements, as well as the maximum height differences.

The two MER rovers and the MSL rover use a more sophisticated evaluation of the safety of the rovers along a large number of candidate arcs from its current location. Many other algorithms for perception of terrain hazards have been used with reasonable success by various organizations. Today it is probably fair to say that the *unsolved problems* lie not in the area of geometric hazards (e.g., hazards that can be evaluated completely based on accurate knowledge of the shape of the terrain) but rather in the area of nongeometric hazards (e.g., hazards where uncertainties in

the load-bearing or frictional properties of the terrain determine the safety of a proposed traverse). Accurate estimation of load-bearing or friction properties of terrain by remote sensing is a very challenging task that will not be completely *solved* anytime soon, if ever.

55.2.5 Estimation

Most estimation for planetary surface exploration relates to the internal state of the robot, or its position, pose and kinematic configuration with respect to the environment. Internal state sensors such as encoders on any active or passive articulations in the vehicle are used, along with a kinematic model and inertial sensors such as accelerometers and gyroscopes, to estimate the pose of the vehicle in inertial space. Perceptual algorithms such as surface reconstruction from clouds of range-points as developed by stereo vision put terrain geometry estimates into this same representation. Heading in inertial space is generally the most difficult to reliably estimate, due to the lack of navigation aids such as the global positioning system, or any easily measured heading reference such as a global magnetic field. Integration of rate-gyro data is used to maintain local attitude during motion while accurate estimation of the rotation axis for Mars is possible by long integrations of 3 axis rate-gyro data while the vehicle is stopped. Similar approaches are probably not feasible for the Moon, because of its slow rotation rate. Imaging of the solar disk or constellations of stars at precisely known times can be combined with stored models of the rotation of the planet to allow accurate estimation of the complete pose of the vehicle in inertial space. Kalman filtering or related techniques are generally employed to reduce the effects of measurement noise.

55.3 Mathematical Modeling

Broadly speaking, both on-orbit manipulators and surface mobile robots are considered to be common articulated body systems with a moving base. One point that clearly distinguishes them from other ground-based robots, such as industrial manipulators, is the existence of a moving base.

55.3.1 Space Robot as an Articulated Body System

The robotic systems discussed in this chapter comprise one or multiple articulated limbs mounted on a base body that has a dynamic coupling with these limbs.

55.2.6 Manipulators for In-Situ Science

The Mars exploration rovers were the first planetary exploration vehicles to have general-purpose manipulators. (Lunokhod had a single-purpose soil penetrometer, and Sojourner had a single degree-of-freedom device to place an Alpha-Proton X-Ray spectrometer in direct contact with the terrain.) The MER arms each have 5°-of-freedom and a reach of over 1 m. Accurate gravity-sag models of the lightweight arm allow the precise position to be predicted in advance of any command to deploy an instrument, and contact sensors allow the arm to stop before any excessive forces build up in the relatively flexible arm. Future arms for planetary surface operations, especially any proposed assembly, maintenance, or servicing tasks as part of the proposed lunar outpost, will require force sensing to protect the stronger but much more rigid arms from damage, as well as to allow controlled forces to be applied to the terrain or workpieces. Of course, there is a huge body of knowledge associated with industrial robot arms, and undersea robotics (e.g., for the offshore oil industry), but such arms are generally very heavy, fast, and stiff compared with credible systems for planetary surface use. Delicate force control has rarely been applied to industrial settings. Space hardware is necessarily very lightweight, and so both the arms and the workpieces will need to have well-resolved force sensing and control to prevent damage to one or both. Because of severe limits on both mass and power, and to avoid unnecessary risk, space manipulation tends to be slow. Historically, this means the gear ratio between each motor and the corresponding output shaft is very large, making the use of motor current as an estimator for output torque very problematic. Other low-mass and robust means for accurate sensing of applied forces in the space environment are needed.

Typical styles of such moving base systems are categorized into the following groups [55.46].

Free-Floating Manipulator Systems

A space free-flyer that has one or more manipulator arms, as illustrated schematically in Fig. 55.22a, is a typical example of this group. When operating the manipulator arm(s), the position and orientation of the base spacecraft fluctuates due to the manipulator reaction. The kinetic momentum of the system is conserved if no external forces or moments are applied, and the conservation law for this system governs the reaction dynamics. Coordination or isolation, between the base

Fig.55.22a–d Four basic types for moving base robots: (a) Free-floating manipulator system, (b) macro–micro manipulator system, (c) flexible structure-based manipulator system, and (d) surface locomotive robot system

and manipulator dynamics is key to advanced motion control.

Macro–Micro Manipulator Systems

A robotic system that comprises a relatively small arm (microarm) for fine manipulation mounted on a relatively large arm (macro-arm) for coarse positioning, is called a macro–micro manipulator system. The **SSRMS** (Canadarm2) and the **SPDM** (Dextre) system, as well as the **JEMRMS** on the Japanese module of the **ISS**, are good examples. Here, the connecting interface at the end point of the macro arm or the root of the micro arm is modeled as the base body (Fig. 55.22b). A free-flying space robot may be treated in this group when its base body is actively controlled by actuators that produce ex-

ternal forces and moments, such as gas-jet thrusters. In this case, these actuators can be modeled as a virtual macro-arm [55.47].

Flexible–Based Manipulator Systems

If the macro arm behaves as a passive flexible (elastic) structure in a macro–micro manipulator system, the system is considered to be a flexible-based manipulator (Fig. 55.22c). Such a situation can be observed in the operation of the **ISS**, when the **SSRMS** is servo or brake locked after its coarse operation. Here, the issue is that the base body (the root of the micro arm, or the end of the macro arm, according to the definition above) is subject to vibrations that will be excited by the reaction of the micro arm.

Mobile Robots with Articulated Limbs

Mobile robots for surface locomotion have the same structure in terms of the dynamics equation as the above groups. This group includes wheeled vehicles, walking (articulated limb) robots, and their hybrids. In a wheeled vehicle, suspension mechanisms, if any, are also modeled as articulated limb systems. The forces and moments yielded by contact with ground, or planetary surface, govern the motion of the system (Fig 55.22d).

55.3.2 Equations for Free-Floating Manipulator Systems

Let us first consider a free-floating system with a single or multiple manipulator arm(s) mounted on a base spacecraft. The pioneering work in the mathematical models of this type of space manipulator systems were conducted in late 1980s and early 1990s and collected in the book [55.48], published in 1993. In this section, the models that are widely accepted today are introduced.

The base body, termed link 0, is floating in inertial space without any external forces or moments. At the end point of the arm(s), external forces/moments may apply. For such a system, the equation of motion is expressed as follows

$$\begin{pmatrix} \mathbf{H}_b & \mathbf{H}_{bm} \\ \mathbf{H}_{bm}^T & \mathbf{H}_m \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{x}}_b \\ \ddot{\boldsymbol{\phi}} \end{pmatrix} + \begin{pmatrix} \mathbf{c}_b \\ \mathbf{c}_m \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \boldsymbol{\tau} \end{pmatrix} + \begin{pmatrix} \mathbf{J}_b^T \\ \mathbf{J}_m^T \end{pmatrix} \mathbf{F}_h. \quad (55.1)$$

The kinematic relationship among \mathbf{x}_h , \mathbf{x}_b , and $\boldsymbol{\phi}$ is expressed using Jacobian matrices as

$$\dot{\mathbf{x}}_h = \mathbf{J}_m \dot{\boldsymbol{\phi}} + \mathbf{J}_b \dot{\mathbf{x}}_b, \quad (55.2)$$

$$\ddot{\mathbf{x}}_h = \mathbf{J}_m \ddot{\boldsymbol{\phi}} + \dot{\mathbf{J}}_m \dot{\boldsymbol{\phi}} + \mathbf{J}_b \ddot{\mathbf{x}}_b + \dot{\mathbf{J}}_b \dot{\mathbf{x}}_b. \quad (55.3)$$

Where the notations are listed as follows:

- $\mathbf{x}_b \in \mathbb{R}^6$: position/orientation of the base
- $\phi \in \mathbb{R}^n$: joint angle of the arm
- $\mathbf{x}_h \in \mathbb{R}^{6k}$: position/orientation of the end point(s)
- $\tau \in \mathbb{R}^n$: joint torque of the arm
- $\mathbf{F}_h \in \mathbb{R}^{6k}$: external forces/moments on the end point(s)
- n : number of total joints
- k : number of manipulator arms,

and \mathbf{H}_b , \mathbf{H}_m , and \mathbf{H}_{bm} are inertia matrices for the base body, manipulator arm, and the coupling between the base and the arm, respectively, and \mathbf{c}_p and \mathbf{c}_q are nonlinear Coriolis and centrifugal forces, respectively.

For a free-floating manipulator in orbit, the gravity forces exerted on the system can be neglected, and so the nonlinear term becomes

$$\mathbf{c}_b = \dot{\mathbf{H}}_b \dot{\mathbf{x}}_b + \dot{\mathbf{H}}_{bm} \dot{\phi}.$$

Integrating the upper set of equation in (55.1) with respect to time, we obtain the total momentum of the system as

$$\mathcal{L} = \int \mathbf{J}_b^T \mathbf{F}_h dt = \mathbf{H}_b \dot{\mathbf{x}}_b + \mathbf{H}_{bm} \dot{\phi}. \quad (55.4)$$

For the case in which reaction wheels are mounted on the base body, they are included as additional manipulator arms.

55.3.3 Generalized Jacobian and Inertia Matrices

From (55.2) and (55.4), the coordinates of the manipulator base $\dot{\mathbf{x}}_b$, which are passive and unactuated coordinates, can be eliminated, as follows

$$\dot{\mathbf{x}}_h = \hat{\mathbf{J}} \dot{\phi} + \dot{\mathbf{x}}_{h0}, \quad (55.5)$$

where

$$\hat{\mathbf{J}} = \mathbf{J}_m - \mathbf{J}_b \mathbf{H}_b^{-1} \mathbf{H}_{bm}, \quad (55.6)$$

and

$$\dot{\mathbf{x}}_{h0} = \mathbf{J}_b \mathbf{H}_b^{-1} \mathcal{L}. \quad (55.7)$$

Since \mathbf{H}_b is the inertia tensor of a single rigid body (the manipulator base), it is always positive definite, and so its inverse exists.

The matrix $\hat{\mathbf{J}}$ was first introduced in [55.49, 50] and is referred to as the *generalized jacobian matrix*. In its original definition, it was assumed that no external

forces/moments acted on the system. If $\mathbf{F}_h = \mathbf{0}$, then the term $\dot{\mathbf{x}}_{h0}$ becomes constant, and, in particular, if the system has zero initial momentum $\dot{\mathbf{x}}_{h0} = \mathbf{0}$, then (55.5) becomes simple. However, note that in the derivation of (55.6), zero or constant momentum is not a necessary condition.

Using this matrix, the manipulator hand can be operated under a resolved motion-rate control or resolved acceleration control in inertial space. Thanks to the generalized Jacobian, although the reactive base motion occurs during the operation, the hand is not disturbed by the motion.

From the upper and lower sets of equations in (55.1), $\ddot{\mathbf{x}}_b$ can be eliminated to obtain the following expression

$$\hat{\mathbf{H}} \ddot{\phi} + \hat{\mathbf{c}} = \tau + \hat{\mathbf{J}} \mathbf{F}_h, \quad (55.8)$$

where

$$\hat{\mathbf{H}} = \mathbf{H}_m - \mathbf{H}_{bm}^T \mathbf{H}_b^{-1} \mathbf{H}_{bm}. \quad (55.9)$$

The matrix $\hat{\mathbf{H}}$ is known as the *generalized inertia matrix* for space manipulators [55.48]. This matrix represents the inertia property of the system in the joint space and can be mapped onto the Cartesian space using the generalized Jacobian matrix

$$\hat{\mathbf{G}} = \hat{\mathbf{J}} \hat{\mathbf{H}}^{-1} \hat{\mathbf{J}}^T. \quad (55.10)$$

The matrix $\hat{\mathbf{G}}$ is referred to as the *inversed inertia tensor* for space manipulators and is useful for the discussion of impact dynamics when a space manipulator collides with or captures a floating target in orbit [55.51].

The generalized Jacobian matrix (**GJM**) is a useful concept, with which the manipulator end point can perform positioning or trajectory tracking control by a simple control algorithm regardless of the attitude deviation during the operation.

A simplified laboratory demonstration was carried out using a two-dimensional free-floating test bed called *EFFORTS* [55.52]. To simulate the motion in a microgravity environment, a robot model was floated on a thin film of pressurized air on a horizontal plate, so that frictionless motion with momentum conservation was achieved.

Figure 55.23 depicts the test bed and a typical experimental result. For Fig. 55.23b, the control command was given to the floating robot by

$$\dot{\phi} = \hat{\mathbf{J}}^{-1} \dot{\mathbf{x}}_d, \quad (55.11)$$

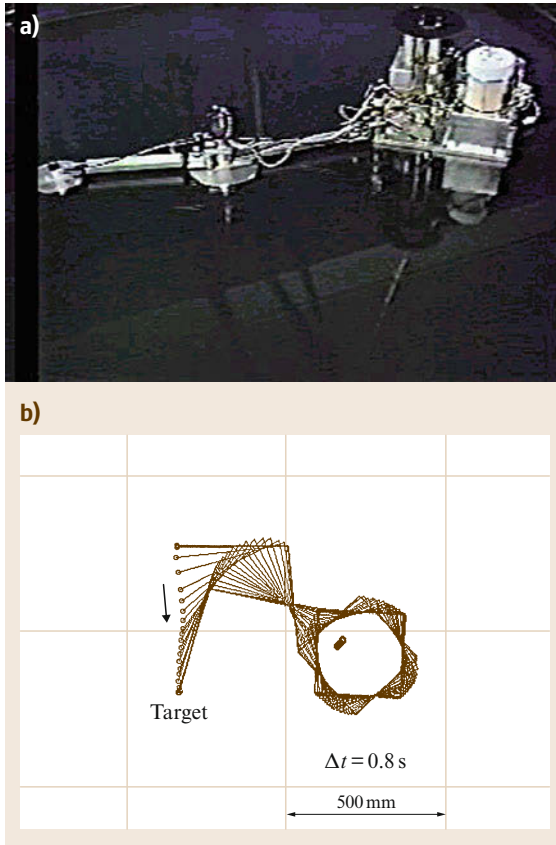

Fig.55.23a,b Laboratory test bed for a free-floating space robot: (a) The EFFORTS test bed, (b) a target capture result

where $\dot{\mathbf{x}}_d$ is the desired velocity of the manipulator end point, the value of which was given and updated by on-line measurement of the end point position \mathbf{x}_h and the target position \mathbf{x}_t , as follows

$$\dot{\mathbf{x}}_d = \frac{\mathbf{x}_t - \mathbf{x}_h}{\Delta t}, \quad (55.12)$$

where Δt is the time interval of the on-line control loop. The desired end point velocity was simply resolved into the joint velocity by (55.11).

The result clearly shows that the manipulator end point properly reached the target in an optimum manner, although the robot base rotated considerably due to the manipulator reaction. Note that, since the target was stationary in this example, the resulting motion trace was a straight line. However, thanks to the on-line control, the manipulator was also able to track and reach a moving target with the same control law.

The validity and effectiveness of the GJM-based manipulator control were also demonstrated in orbit by Japanese ETS-VII mission [55.14].

55.3.4 Linear and Angular Momenta

The integral of the upper set of equation in (55.1) gives a momentum equation, as shown in (55.4), which is composed of the linear and angular momenta. The linear part is expressed as

$$\tilde{\mathbf{H}}_b \mathbf{v}_b + \tilde{\mathbf{H}}_{bm} \dot{\boldsymbol{\phi}} = \mathbf{P}, \quad (55.13)$$

where \mathbf{v}_b is the linear velocity of the base, \mathbf{P} is the initial linear momentum, and the inertia matrices with the mark of (\sim) are the corresponding components for the linear momentum [55.48]. When the linear momentum is further integrated, the result verifies the principle that the mass centroid of the entire system either remains stationary or translates with a constant velocity.

The angular momentum equation, however, does not have a second integral, and therefore provides a first-order nonholonomic constraint [55.53]. The equation can be expressed as

$$\tilde{\mathbf{H}}_b \boldsymbol{\omega}_b + \tilde{\mathbf{H}}_{bm} \dot{\boldsymbol{\phi}} = \mathbf{L}, \quad (55.14)$$

where $\boldsymbol{\omega}_b$ is the angular velocity of the base, \mathbf{L} is the initial angular momentum, and the inertia matrices with the mark of (\sim) are the corresponding components for the angular momentum [55.48]; $\tilde{\mathbf{H}}_{bm} \dot{\boldsymbol{\phi}}$ represents the angular momentum generated by the manipulator motion.

Equation (55.14) can be solved for $\boldsymbol{\omega}_b$ with zero initial angular momentum

$$\boldsymbol{\omega}_b = -\tilde{\mathbf{H}}_b^{-1} \tilde{\mathbf{H}}_{bm} \dot{\boldsymbol{\phi}}. \quad (55.15)$$

This expression describes the resulting disturbance motion of the base when there is joint motion $\dot{\boldsymbol{\phi}}$ in the manipulator arm.

There are a number of points worth discussion when analyzing this equation. The magnitudes and directions of the maximum and minimum disturbances can be obtained from the singular value decomposition of the matrix $(-\tilde{\mathbf{H}}_b^{-1} \tilde{\mathbf{H}}_{bm})$ and displayed on the map. Such a map is called a *disturbance map* [55.54, 55]. Equation (55.15) is also used for the feed-forward compensation in the coordinated manipulator/base control model [55.56, 57].

55.3.5 Virtual Manipulator

The concept of the *virtual manipulator (VM)* is an augmented kinematic representation that considers the base motion due to reaction forces or moments. The model is based on the fact that the mass centroid of the entire system does not move in the free-floating system without any external forces [55.58]. The mobility

of the end point of the arm is decreased by the base motion. In the **VM** representation, such mobility degradation is expressed by virtually shrinking the length of the real arm according to the mass property. Note that the **VM** considers only linear momentum conservation. If the differential expression of **VM** is obtained using a Jacobian matrix, the Jacobian is not a conventional kinematic Jacobian, but rather a version of the generalized Jacobian defined by the combination of the kinematic equation (55.2), and the linear momentum equation (55.13).

55.3.6 Dynamic Singularity

Dynamic singularities are singular configurations in which the manipulator end point loses mobility in some inertial direction [55.59]. Dynamic singularities are not found in earth-based manipulators, but rather occur in free-floating space manipulator systems due to the coupling dynamics between the arm and the base. Dynamic singularities coincide with the singularities of the generalized Jacobian matrix determined by (55.6). The singular value decomposition (**SVD**) of a manipulator Jacobian matrix provides *manipulability* analysis. Likewise, the **SVD** of the generalized Jacobian matrix yields the manipulability analysis of a free-floating space manipulator [55.60]. Figure 55.24 shows the comparison of the manipulability distribution between a 2-DOF ground-based manipulator and a 2-DOF floating manipulator, from which the degradation of the manipulability is observed in the space arm due to the dynamic coupling.

55.3.7 Reaction Null-Space (RNS)

From a practical point of view, any change in the base attitude is undesirable. As such, manipulator motion planning methods that minimize the base attitude disturbance have been investigated extensively. Analysis of the angular momentum equation reveals that the ultimate goal of achieving zero disturbance is possible.

The following is the angular momentum equation with zero initial angular momentum $\mathbf{L} = \mathbf{0}$ and the zero attitude disturbance $\omega_b = \mathbf{0}$ given in (55.14)

$$\tilde{\mathbf{H}}_{bm}\dot{\boldsymbol{\phi}} = \mathbf{0}. \quad (55.16)$$

This equation yields the following null-space solution

$$\dot{\boldsymbol{\phi}} = (\mathbf{I} - \tilde{\mathbf{H}}_{bm}^+ \tilde{\mathbf{H}}_{bm})\dot{\boldsymbol{\zeta}}. \quad (55.17)$$

The joint motion given by (55.17) is guaranteed not to disturb the base attitude. Here, the vector $\dot{\boldsymbol{\zeta}} \in \mathbb{R}^n$ is arbitrary and the null-space of the inertia matrix $\tilde{\mathbf{H}}_{bm} \in \mathbb{R}^{3 \times n}$ is called the *reaction null-space (RNS)* [55.61].

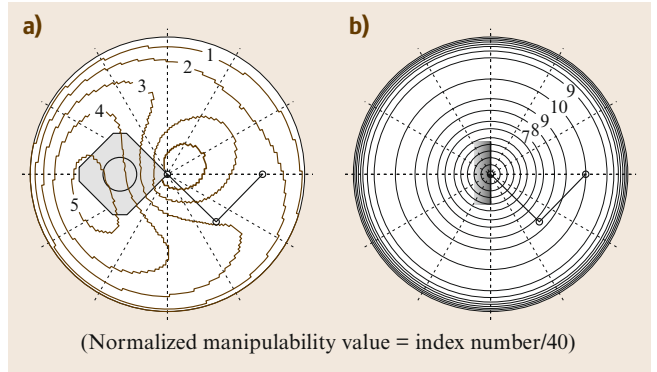

Fig.55.24a,b Manipulability distribution in the work space (after [55.60])

The **DOF** for $\dot{\boldsymbol{\zeta}}$ is $n - 3$. For example, if a manipulator arm mounted on a free-floating space robot has 6-DOF, i. e., $n = 6$, then 3-DOF remain in the reaction null-space. These **DOFs** can be specified by introducing additional motion criteria, such as end point positioning of the arm. Such manipulator operation that produces no reaction in the base is called the *reactionless manipulation* [55.62].

The validity and effectiveness of the RNS-based reactionless manipulation were demonstrated in orbit by Japanese **ETS-VII** mission [55.14].

55.3.8 Motion Planning Issues

This subsection addresses the generation of feasible trajectories for a free-flying robot for executing typical point-to-point or grasping tasks. The subject falls under the problem domain of motion planning, with the aim of satisfying motion constraints which generally cannot be satisfied with use of local methods alone (feedback control and model predictive control). A trajectory resulting from the motion planning is fed to a tracking controller, which accounts for any modeling errors, to accomplish the task in question. This approach also aims at providing autonomous skills for supporting a human ground operator.

A typical task of interest here is that of a point-to-point maneuver of a robot manipulator mounted on a servicer satellite, to bring its end-effector in some desired inertial position and orientation. This task may require actuation of the servicer, or may, if possible, be preferably executed in free-floating mode, to avoid issues related to the use of the on-board thrusters, such as fuel expenditure. In this context, to minimize the attitude change of the servicer resulting from the manipulator motion, a noticeable fundamental result for a point-to-point maneuver, derived from nonlinear optimization theory, is the V-maneuver [55.63]. Intuitively,

the attitude change is minimized by making the robot first move radially inward, toward the system center of mass, before turning and then radially outward, to reach the new desired final position.

A second task that has received much attention is the grasping of a free tumbling target, like a defected satellite. Currently, there are a number of space programs worldwide which are addressing this task, like the preparation of the demonstration mission DEOS of the DLR (Sect. 55.1.2) for grasping a small satellite in LEO, the e.Deorbit study of the ESA for the deorbiting of the defected ENVISAT satellite and PHOENIX of DARPA for grasping a geostationary satellite in the graveyard orbit. Different approaches can be found in the literature to tackle this problem, to include [55.64, 65] for feedback control, [55.66] for model predictive control, [55.67] for optimal control in Cartesian space and [55.68] for nonlinear optimization, to mention some.

Due to the nonholonomic nature of the dynamics of a free-floating robot (Sect. 55.3.4), in order to satisfy all relevant motion constraints, the motion planning problems above can only be solved through numerical integration. Note in fact, that the final system configuration for a given final end-effector position in inertial space is function of the whole path taken by the robot throughout the motion.

Principally, the motion planning tasks above may be formulated as an optimal control problem of the type

$$\min_{t_f, \phi(t)} \Gamma(\phi(t), \tau(t), t_f), \quad (55.18)$$

subject to

$$g(t_f, \phi(t)) = 0 \quad (55.19)$$

$$h(t_f, \phi(t)) \leq 0, \quad (55.20)$$

for $0 \leq t \leq t_f$ and where t_f is the final time; $\phi(t)$ is the vector of joint positions; $\tau(t)$ is the vector of joint torques; Γ is a predefined cost function; g are equality constraints to include, for example, the state transition equations; h are inequality constraints, for example the joint box constraints on position, velocity and torque, or collision avoidance constraints. Other motion constraints may include inequality constraints on the end-effector forces during contact, or other operational constraints.

This consists of an infinite dimensional problem, in the given time interval, which generally cannot be solved in closed form. The direct shooting optimization methods lend themselves well to solving these problems iteratively [55.69], where for example the independent DOF (in the case of a free-floating system,

the robot joint angles) are parameterized in time as

$$\phi = \phi(t, p) \quad (55.21)$$

with $p \in \mathbb{R}^n$, for n optimization parameters, where ϕ may be a polynomial function, a B-spline function, or any other. This way, the problem becomes that of finding a suitable value for the parameters p which satisfies all motion constraints (feasibility), as well as perhaps minimizes a cost function (optimality), like the time-to-collision [55.70], the end time [55.67], or the mechanical energy [55.68]. The problem is as such transformed into a finite dimensional problem and can be solved as a nonlinear programming problem (NLP) with classical numerical iterative methods such as sequential quadratic programming (SQP).

For example, for a Cartesian point-to-point problem, we have the following supplementary equality constrains at the end time

$$X^c = \int_0^{t_f} \hat{\mathbf{J}} \dot{\phi}(t, p) dt = X_{\text{des}}^c, \quad (55.22)$$

where $X^c \in \mathbb{R}^n$ denotes the end-effector pose (array matrix of dimension $\text{DOF}_e \times 1$). Note that the constraint itself has $\infty^{\text{DOF}+3-\text{DOF}_e}$ solutions for the system configuration (for DOF robot joints), however these all imply a specific base body attitude as well as a specific robot configuration. Solving the problem of reaching a specific system configuration is a hard nonholonomic control problem, which is avoided by solving the constraint thorough the integral above and an adequate parameter set p .

Extensions of this are necessary to treat the grasping task. The latter can ideally be separated into three phases: approach, tracking and, stabilization. The first comprises a point-to-point maneuver, however with a nonzero end velocity. The second comprises a tracking maneuver, in which the Cartesian motion of the robot end-effector is dictated by the tumbling motion and the geometry of the target as it follows the grasping point and homes in onto it, to finally grasp it. Note that this phase aims at minimizing the impact between the end-effector and the target. The third phase involves a robot joint velocity decay maneuver, once the target is grasped. This formulation results in a multiple-phase problem, for which the boundaries between the phases introduce supplementary motion constraints in the motion planning problem.

From a methodological point of view, note that there is no simple measure to determine if and when the grasping point on the target will be reachable from the current robot configuration (Fig. 55.25) and whether

Fig. 55.25 Orbital scenario: servicer satellite with 7-DOF manipulator and target satellite with solar panels. Coordinate system of a predefined grasping point on target ring shown

the trajectory which derives from a local control law will be feasible at all times (accounting for the motion constraints listed above). It is also necessary to provide information on the time synchronization between the motion of the grasping point on the target and that of the robot. Furthermore, the nonlinear nature of the robot kinematics needs to be exploited to favor a successful grasp. These considerations speak in favor of the use of a reference trajectory, which is computed off-line by means of a global search, based on a motion prediction of the target and on a geometric model of the same target and of the space robot [55.68].

It is also well known that optimization methods suffer from convergence issues (arising from local minima), if a judicious initial guess is not available. It is for this reason that a look-up table approach is necessary [55.68] in order to provide a sufficiently high probability of convergence for a given grasping task.

The necessity of a look-up table also arises from the long computation times of the optimization process, which result from the aforementioned necessity to integrate the equations of motion for any given optimization iteration. This time is generally reduced if a solution close to the sought one is given as a starting point. An attempt to eliminate the necessity of integrating the equations of motion was also made in [55.71], where a differentially flat representation for a free-floating robot was sought. In such a formulation, there are as many differential equations as there are independent state variables, or flat variables, and as such, any parameterization of the flat variables is solution of the equations of motion. Such a representation was found for the case in which the robot has three joints and the center of mass of its load lies on the rotation axis of the last joint.

It is also of interest to make some considerations on practical technological issues which can influence one or the other future research direction. With regard to the minimization of the servicer attitude change during robotic operations, it is worth realizing that this is generally only an issue for maintaining the communication link from low Earth orbit with a geostationary satellite, for which a high pointing accuracy is required (note that for a communication link from low Earth orbit to ground instead, an omnidirectional antenna is sufficient). Therefore, rather than limiting the robot workspace to its reaction null-space to avoid any attitude change at all, in which case the resulting robot movements would generally be confined to the extent of becoming of little practical use, a simple technological solution is possible through the implementation of a gimbal joint for the communication antenna on the servicer.

Another simple technological solution to a theoretically involved problem is that of controlling the attitude of the servicer by means of adequate closed-loop maneuvers of the robot. As is well known, reaction wheels on a satellite achieve the same result, also with the same principle of momentum transfer, but however with a far simpler control law than that necessary for a robot. It is then important to realize that, although reaction wheels were until today far too small for any useful robotic application, larger reaction wheels are currently being developed, for example, in the context of the BIROS mission of the DLR, which is planned to fly in 2014. Although these will still not be able to fully compensate the typical robot dynamic coupling terms (if wanting to fully stabilize the servicer attitude), they will however be able to allow significant attitude slew maneuvers of the servicer quickly, without having to resort to the use of the robot or of the thrusters. Furthermore, they will be useful to reduce the robot singularities, due to the enhanced system's actuation.

55.3.9 Equations for Flexible-Based Manipulator Systems

Next, let us consider a flexible-based manipulator system in which a single or multiple manipulator arm(s) are supported by a flexible beam or a spring and damper (visco-elastic) system. For such a system, the equation of motion is obtained using the following variables:

- $\mathbf{x}_b \in \mathbb{R}^6$: position/orientation of the base
- $\phi \in \mathbb{R}^n$: joint angle of the arm
- $\mathbf{x}_h \in \mathbb{R}^{6k}$: position/orientation of the end point(s)
- $\mathbf{F}_b \in \mathbb{R}^6$: forces/moments to deflect the flexible base
- $\boldsymbol{\tau} \in \mathbb{R}^n$: joint torque of the arm
- $\mathbf{F}_h \in \mathbb{R}^{6k}$: external force/torque on the end point(s).

$$\begin{pmatrix} \mathbf{H}_b & \mathbf{H}_{bm} \\ \mathbf{H}_{bm}^T & \mathbf{H}_m \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{x}}_b \\ \ddot{\boldsymbol{\phi}} \end{pmatrix} + \begin{pmatrix} \mathbf{c}_b \\ \mathbf{c}_m \end{pmatrix} = \begin{pmatrix} \mathbf{F}_b \\ \boldsymbol{\tau} \end{pmatrix} + \begin{pmatrix} \mathbf{J}_b^T \\ \mathbf{J}_m^T \end{pmatrix} \mathbf{F}_h, \quad (55.23)$$

$$\dot{\mathbf{x}}_h = \mathbf{J}_m \dot{\boldsymbol{\phi}} + \mathbf{J}_b \dot{\mathbf{x}}_b, \quad (55.24)$$

$$\ddot{\mathbf{x}}_h = \mathbf{J}_m \ddot{\boldsymbol{\phi}} + \dot{\mathbf{J}}_m \dot{\boldsymbol{\phi}} + \mathbf{J}_b \ddot{\mathbf{x}}_b + \dot{\mathbf{J}}_b \dot{\mathbf{x}}_b. \quad (55.25)$$

Here, with the gravitational force \mathbf{g} in Cartesian space, the term \mathbf{c}_b is generally expressed as

$$\mathbf{c}_b = \mathbf{f}(\mathbf{x}_b, \boldsymbol{\phi}, \dot{\mathbf{x}}_b, \dot{\boldsymbol{\phi}}) + \mathbf{g}(\mathbf{x}_b, \boldsymbol{\phi}). \quad (55.26)$$

The difference from the equation of a free-floating manipulator system (55.1) is the existence of the base constraint force \mathbf{F}_b . Let \mathbf{D}_b and \mathbf{K}_b be the matrix representing the damping and spring factors, respectively, of the flexible-base. The constraint forces and moments \mathbf{F}_b are then expressed as

$$\mathbf{F}_b = -\mathbf{D}_b \dot{\mathbf{x}}_b - \mathbf{K}_b \Delta \mathbf{x}_b. \quad (55.27)$$

Since the base is constrained, the total momentum is not conserved, and it might be meaningless to check the system momentum. However, it is important to consider the partial momentum \mathcal{L}_m for the part of the manipulator arm

$$\mathcal{L}_m = \mathbf{H}_{bm} \dot{\boldsymbol{\phi}}, \quad (55.28)$$

which is termed the *coupling momentum* [55.72]. Its time derivative describes the forces and moments \mathbf{F}_m , which are yielded by the dynamic reaction from the manipulator arm to the base

$$\mathbf{F}_m = \mathbf{H}_{bm} \ddot{\boldsymbol{\phi}} + \dot{\mathbf{H}}_{bm} \dot{\boldsymbol{\phi}}. \quad (55.29)$$

Using \mathbf{F}_b and \mathbf{F}_m , the upper set of equation in (55.23) is rearranged as

$$\mathbf{H}_b \ddot{\mathbf{x}}_b + \mathbf{D}_b \dot{\mathbf{x}}_b + \mathbf{K}_b \Delta \mathbf{x}_b = -\mathbf{g} - \mathbf{F}_m + \mathbf{J}_b^T \mathbf{F}_h. \quad (55.30)$$

Equation (55.23) or (55.30) is a familiar expression for flexible-base manipulators [55.73, 74].

55.3.10 Advanced Control for Flexible Structure Based Manipulators

In this subsection, advanced control issues for a macro-micro space manipulator are discussed. The SSRMS attached to the SPDM (Fig. 55.4) and the JEMRMS (Fig. 55.5) are examples. Operation modes for this class of space manipulators include coarse motion by the macro (long-reach) component and fine manipulation

by the micro component. In normal cases, these two control modes are executed exclusively. Namely, while one component is active the other component should be servo (or brake) locked. Thus, during the operation of the micro component, the macro component behaves just as a passive base.

Due to the flexible nature of the space long-reach arm, the macro part is subject to vibrations. These vibrations can be excited during coarse positioning and may remain for a long time after each operation. In fine manipulation, the macro arm behaves as a passive flexible structure, but then vibrations can be excited by reactions from the motion of the micro arm. These motions degrade the control accuracy and operational performance of the system. In practice, the booms are usually sufficiently stiff, but flexibility comes mainly from the low stiffness at the joints and gear trains. Moreover, lightweight and microgravity characteristics make the structure sensitive to yield vibrations, and the surrounding vacuum, or the lack of air viscosity, provides a reduced damping effect to the structure.

Conventionally, the vibration issue has been managed for SRMS and SSRMS by the operational skill of well-trained astronauts and by limiting the maximum operational velocity according to the inertia of the handling object. However, if an advanced controller is introduced on the ISS, the training time for astronauts will be reduced and the operational speed can be increased.

Here, the following two subtasks are considered in dealing with this issue:

- Suppression of the vibrations of the flexible base
- End point control in the presence of vibrations.

To suppress the vibrations of the macro arm (flexible base), the coupled dynamics is effectively used. Such control is called *coupled vibration suppression control* [55.75]. The coupled dynamics is a solution space of the micro arm motion with maximum coupling with the vibration dynamics of the macro arm. Note that this solution space is perpendicular to the reaction null-space introduced in Sect. 55.3.7. Since the spaces are orthogonal, the coupled vibration suppression control and reactionless manipulation can be superimposed without any mutual interference.

The motion command of the micro arm to suppress the vibrations is determined with a feedback of the linear and angular velocity of the end point of the macro arm $\dot{\mathbf{x}}_b$

$$\ddot{\boldsymbol{\phi}} = \mathbf{H}_{bm}^+ \mathbf{H}_b \mathbf{G}_b \dot{\mathbf{x}}_b, \quad (55.31)$$

where $(\cdot)^+$ denotes the right pseudo-inverse, and \mathbf{G}_b is a positive definite gain matrix.

If written in the form of a joint torque input, the vibration control law is expressed as follows

$$\tau = \mathbf{H}_m \mathbf{H}_{bm}^+ \mathbf{G}_b \dot{\mathbf{x}}_b. \quad (55.32)$$

In the presence of redundancy in the micro arm, (55.31) can be extended to control with a null-space component

$$\ddot{\phi}_m = \mathbf{H}_{bm}^+ (\mathbf{H}_b \mathbf{G}_b \dot{\mathbf{x}}_b - \dot{\mathbf{H}}_{bm} \dot{\phi}_m) + \mathbf{P}_{RNS} \zeta, \quad (55.33)$$

where ζ is an n -DOF arbitrary vector and $\mathbf{P}_{RNS} = (\mathbf{E} - \mathbf{H}_{bm}^+ \mathbf{H}_{bm})$ is a projector onto a null space of the coupling inertia matrix \mathbf{H}_{bm} . When the micro arm is operated using (55.33), the closed-loop system is expressed as

$$\mathbf{H}_b \ddot{\mathbf{x}}_b + \mathbf{H}_b \mathbf{G}_b \dot{\mathbf{x}}_b + \mathbf{K}_b \Delta \mathbf{x}_b = \mathbf{F}_b + \mathbf{J}_b^T \mathbf{F}_h. \quad (55.34)$$

Equation (55.34) represents a second-order damped vibration system. With no force input, i.e., $\mathbf{F}_b = \mathbf{F}_h = 0$, the vibrations converge to zero with a proper choice of the gain matrix \mathbf{G}_b .

For the determination of vector ζ , feedback control to reduce the positioning error of the micro arm end point is considered. The error vector is defined as

$$\tilde{\mathbf{x}}_h = \mathbf{x}_h^d - \mathbf{x}_h. \quad (55.35)$$

After some derivation, the control law for the joint torque of the micro arm is obtained in the following form [55.75, 76]

$$\tau = ((\mathbf{J}_m^T)^+ \mathbf{H}_m \mathbf{P}_{RNS})^+ (\mathbf{K}_p \tilde{\mathbf{x}}_h - \mathbf{K}_d \mathbf{J}_m \dot{\phi}) - \mathbf{G}_m \dot{\phi}, \quad (55.36)$$

where \mathbf{K}_p , \mathbf{K}_d , and \mathbf{G}_m are positive definite gain matrices.

Figure 55.26 shows a block diagram for the control system described by (55.32) and (55.36).

As a simplified demonstration, a planar system with a four-joint redundant manipulator arm atop a flexible beam is considered. Figure 55.27 shows the vibration amplitude of the flexible beam after an impulsive external force. The graph labeled *w/o vs* depicts the vibrations of the beam without any manipulator control but with natural damping. The graph labeled *with vs* depicts the case in which vibration suppression control given by (55.32) is applied, where the vibrations are damped quickly.

In addition, Fig. 55.28 shows the end point motion of the manipulator arm during the control. The graph labeled *w/o RNS* is the case of using (55.32), where the base vibrations were successfully suppressed but

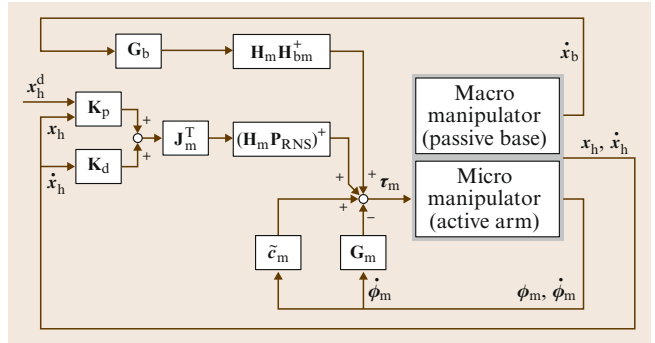

Fig. 55.26 Block diagram for simultaneous vibration suppression and manipulator end point control for a flexible-structure-mounted manipulator system

Fig. 55.27 Vibrations of the flexible base

Fig. 55.28 Positioning error of the manipulator end tip

the position of the manipulator end point was deflected by this suppression behavior. The graph labeled *with RNS* depicts the case in which both vibration suppression control given by (55.32) and the end point control given by (55.36) are applied simultaneously. This last case shows that the vibrations were damped successfully and that the positioning error of the manipulator

end point converged to zero. This is a result of the redundancy of the arm.

Here, note that the proposed control method requires precise information on dynamic characteristics, such as the inertia parameters of the arms and the handled payload, if any. To achieve more practical applications, the proposed method must be extended to schemes for parameter identification [55.77] and adaptive control [55.78], with which the convergence of the control is guaranteed even with imprecise a priori knowledge of the dynamic parameters [55.76].

55.3.11 Contact Dynamics and Impedance Control

The capture and retrieval operation of a floating and tumbling *target*, such as a malfunctioning satellite, by a manipulator arm mounted on a servicing robot (called a *chaser*) can be decomposed into the following three phases:

1. Approaching phase (before contact with the target)
2. Contact/impact phase (at the moment of contact)
3. Post contact phase (after contact or grasping).

If the contact is impulsive, the first and the third phases are discontinued by the impulsive phenomena of the second phase. Understanding of this impulsive phenomena is indispensable when designing a comprehensive capture control scheme. In this subsection, the formulation of impact dynamics is first considered, and impedance control (which is useful to minimize the impact forces and prolong the contact duration) is then discussed.

Let us consider a chain of rigid links composed of $n + 1$ bodies freely floating in inertial space. As discussed in Sect. 55.3.3, the equation of motion for this type of system becomes (55.8). Here, the impulsive contact force is assumed to be applied at the manipulator end tip and is expressed as $\mathbf{F}_h = (\mathbf{f}_h^T, \mathbf{n}_h^T)^T \in \mathbb{R}^6$. This impulsive force also yields a change in the system momenta $(\mathbf{P}_g^T, \mathbf{L}_g^T)^T \in \mathbb{R}^6$, expressed as

$$\begin{aligned} \begin{pmatrix} \dot{\mathbf{P}}_g \\ \dot{\mathbf{L}}_g \end{pmatrix} &= \begin{pmatrix} w\mathbf{E} & 0 \\ 0 & \mathbf{I}_g \end{pmatrix} \begin{pmatrix} \dot{\mathbf{v}}_g \\ \dot{\boldsymbol{\omega}}_g \end{pmatrix} + \begin{pmatrix} 0 \\ \boldsymbol{\omega}_g \times \mathbf{I}_g \boldsymbol{\omega}_g \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{E} & 0 \\ \tilde{\mathbf{r}}_{gh} & \mathbf{E} \end{pmatrix} \begin{pmatrix} \mathbf{f}_h \\ \mathbf{n}_h \end{pmatrix}, \end{aligned} \quad (55.37)$$

where \mathbf{E} is a 3×3 identity matrix, and the symbols with the suffix g indicate the corresponding values observed around the mass centroid of the $n + 1$ link system.

In the above equations, (55.8) describes an internal joint motion (termed *local motion*) of the system,

whereas (55.37) describes the overall motion (termed *global motion*) about the centroid of the system. As a result of force input \mathbf{F}_h , the floating chain induces both the local motion around its articulated joints and the global translation and rotation with respect to the centroid.

From (55.8) and (55.37), the acceleration of the manipulator end tip $\boldsymbol{\alpha}_h$ can be expressed in the inertial frame as

$$\boldsymbol{\alpha}_h = \mathbf{G}^* \mathbf{F}_h + \mathbf{d}^*, \quad (55.38)$$

where

$$\mathbf{G}^* = \hat{\mathbf{J}}\hat{\mathbf{H}}^{-1}\hat{\mathbf{J}}^T + \mathbf{R}_h\mathbf{M}^{-1}\mathbf{R}_h^T, \quad (55.39)$$

$$\mathbf{R}_h = \begin{pmatrix} \mathbf{E} & -\tilde{\mathbf{r}}_{gh} \\ 0 & \mathbf{E} \end{pmatrix}, \quad \mathbf{M} = \begin{pmatrix} w\mathbf{E} & 0 \\ 0 & \mathbf{I}_g \end{pmatrix}, \quad (55.40)$$

and \mathbf{d}^* is a velocity dependent term.

Equations (55.38)–(55.40) are expressions for the motion of the hand (the point at which collision occurs) induced by the impact force \mathbf{F}_h , where the matrix \mathbf{G}^* , which is the augmented version of (55.10), represents the dynamic characteristics of this system.

Further augmentation for the inverted inertia matrix has been discussed for the case in which the contact duration is not considered to be infinitesimal [55.51].

Now let us assume the case in which two free-floating chains, A and B, with dynamic characteristics \mathbf{G}_A^* and \mathbf{G}_B^* collide with each other at their respective hands (end points) and an impact force \mathbf{F}_h is induced by this collision.

The equations of motion at the instance of collision are

$$\mathbf{G}_A^* \mathbf{F}_h = \begin{pmatrix} \dot{\mathbf{v}}_{hA} \\ \dot{\boldsymbol{\omega}}_{hA} \end{pmatrix} - \mathbf{d}_A^* \quad (55.41)$$

for the chain A, and

$$\mathbf{G}_B^* (-\mathbf{F}_h) = \begin{pmatrix} \dot{\mathbf{v}}_{hB} \\ \dot{\boldsymbol{\omega}}_{hB} \end{pmatrix} - \mathbf{d}_B^* \quad (55.42)$$

for the chain B, where the subscripts A and B indicate the label of the chain.

Assuming that \mathbf{G}_A^* and \mathbf{G}_B^* remain constant during the infinitesimal contact duration and the velocity-dependent terms \mathbf{d}_A^* and \mathbf{d}_B^* are small and negligible, integration of (55.41) and (55.42) yields

$$\mathbf{G}_A^* \int_t^{t+\delta t} \mathbf{F}_h dt = \begin{pmatrix} \mathbf{v}'_{hA} \\ \boldsymbol{\omega}'_{hA} \end{pmatrix} - \begin{pmatrix} \mathbf{v}_{hA} \\ \boldsymbol{\omega}_{hA} \end{pmatrix}, \quad (55.43)$$

$$\mathbf{G}_B^* \int_t^{t+\delta t} \mathbf{F}_h dt = \begin{pmatrix} \mathbf{v}_{hB} \\ \boldsymbol{\omega}_{hB} \end{pmatrix} - \begin{pmatrix} \mathbf{v}'_{hB} \\ \boldsymbol{\omega}'_{hB} \end{pmatrix}, \quad (55.44)$$

where $\{\prime\}$ indicates the velocity after the collision. Integration of F_h

$$\bar{F}_h = \lim_{\delta t \rightarrow 0} \int_t^{t+\delta t} F_h dt \quad (55.45)$$

represents the impulse (force-time product) acting on both chains. Providing that the total momenta of the two systems are strictly conserved before and after the collision, we obtain the following expression from (55.43) and (55.44)

$$(\mathbf{G}_A^* + \mathbf{G}_B^*) \bar{F}_h = \left\{ \begin{pmatrix} v'_{hA} \\ \omega'_{hA} \end{pmatrix} - \begin{pmatrix} v'_{hB} \\ \omega'_{hB} \end{pmatrix} \right\} + \left\{ \begin{pmatrix} v_{hB} \\ \omega_{hB} \end{pmatrix} - \begin{pmatrix} v_{hA} \\ \omega_{hA} \end{pmatrix} \right\}. \quad (55.46)$$

In general collision analysis, the coefficient of restitution (elasticity factor) associated with the relative velocities before and after the collision is often employed [55.79]. If we accept this restitution coefficient for 6-DOF linear and angular velocities, the relationship between relative velocities before and after contact becomes

$$\begin{pmatrix} v'_{hA} \\ \omega'_{hA} \end{pmatrix} - \begin{pmatrix} v'_{hB} \\ \omega'_{hB} \end{pmatrix} = \epsilon \left\{ \begin{pmatrix} v_{hB} \\ \omega_{hB} \end{pmatrix} - \begin{pmatrix} v_{hA} \\ \omega_{hA} \end{pmatrix} \right\}, \quad (55.47)$$

where

$$\epsilon \equiv \text{diag}(e_1, \dots, e_6), \quad 0 \leq e_i \leq 1 \quad (55.48)$$

is the restitution coefficient matrix.

Substituting (55.47) into (55.46), the impulse induced by this collision can be expressed only by the relative velocity of two points before the contact

$$\bar{F}_h = (\mathbf{E}_6 + \epsilon) \mathbf{G}_\Sigma^{*-1} \mathcal{V}_{hAB}, \quad (55.49)$$

where

$$\mathbf{G}_\Sigma^* = \mathbf{G}_A^* + \mathbf{G}_B^*, \quad (55.50)$$

$$\mathcal{V}_{hAB} = \begin{pmatrix} v_{hB} \\ \omega_{hB} \end{pmatrix} - \begin{pmatrix} v_{hA} \\ \omega_{hA} \end{pmatrix}. \quad (55.51)$$

Using the introduced notation, the magnitude of impulse is expressed as

$$\|\bar{F}_h\| = \sqrt{(\mathbf{E}_6 + \epsilon)^T \mathcal{V}_{hAB}^T \mathbf{G}_\Sigma^{*-T} \mathbf{G}_\Sigma^{*-1} \mathcal{V}_{hAB} (\mathbf{E}_6 + \epsilon)}, \quad (55.52)$$

and the velocity after collision becomes

$$\begin{pmatrix} v'_{hA} \\ \omega'_{hA} \end{pmatrix} = (\mathbf{G}_A^{*-1} + \mathbf{G}_B^{*-1})^{-1} \times \left[(\mathbf{E}_6 + \epsilon) \mathbf{G}_B^{*-1} \begin{pmatrix} v_{hB} \\ \omega_{hB} \end{pmatrix} + (\mathbf{G}_A^{*-1} - \epsilon \mathbf{G}_B^{*-1}) \begin{pmatrix} v_{hA} \\ \omega_{hA} \end{pmatrix} \right], \quad (55.53)$$

where suffixes A and B are interchangeable.

These expressions are considered to be an augmentation of the impact theory for a two-point-mass system into articulated body systems.

Impedance control is a concept by which we can control the manipulator end tip so as to obtain the desired mechanical impedance characteristics. Such control is useful to alter the dynamic characteristics of the arm during the contact phase. In a special case, the desired impedance of the manipulator end tip (hand) may be tuned to achieve *impedance matching* with the colliding target object so that the hand can easily maintain stable contact with the target [55.80].

Let \mathbf{M}_d , \mathbf{D}_d , and \mathbf{K}_d be the matrices for the desired impedance properties of inertia, viscosity, and stiffness, respectively, measured at the manipulator end point. The equation of motion for the desired system is then expressed as

$$\mathbf{M}_d \ddot{\mathbf{x}}_h + \mathbf{D}_d \Delta \dot{\mathbf{x}}_h + \mathbf{K}_d \Delta \mathbf{x}_h = \mathbf{F}_h. \quad (55.54)$$

From (55.8) and (55.54), the impedance control law for a free-floating manipulator system is obtained as [55.81]

$$\begin{aligned} \tau_h &= \mathbf{H}^* \hat{\mathbf{J}}^{-1} \{ \mathbf{M}_d^{-1} (\mathbf{D}_d \Delta \dot{\mathbf{x}}_h + \mathbf{K}_d \Delta \mathbf{x}_h - \mathbf{F}_h) \\ &\quad - \dot{\hat{\mathbf{J}}} \dot{\phi} - \ddot{\mathbf{x}}_{gh} \} - \hat{\mathbf{J}}^T \mathbf{F}_h + \mathbf{c}^*. \end{aligned} \quad (55.55)$$

The usefulness of the impedance control in free-flying space robots has been discussed in [55.81–83].

55.3.12 Dynamics of Mobile Robots

The equation of motion for a mobile robot that has multiple articulated limbs, such as that shown in Fig. 55.29,

Fig. 55.29 Schematic model of a mobile robot

is given by the following equation

$$\begin{pmatrix} \mathbf{H}_b & \mathbf{H}_{bm1} & \cdots & \mathbf{H}_{bmk} \\ \mathbf{H}_{bm1}^T & \mathbf{H}_{m11} & \cdots & \mathbf{H}_{m1k} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{H}_{bmk}^T & \mathbf{H}_{m1k}^T & \cdots & \mathbf{H}_{mkk} \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{x}}_b \\ \ddot{\boldsymbol{\phi}}_1 \\ \vdots \\ \ddot{\boldsymbol{\phi}}_k \end{pmatrix} + \begin{pmatrix} \mathbf{c}_b \\ \mathbf{c}_{m1} \\ \vdots \\ \mathbf{c}_{mk} \end{pmatrix} = \begin{pmatrix} \mathbf{F}_b \\ \boldsymbol{\tau}_1 \\ \vdots \\ \boldsymbol{\tau}_n \end{pmatrix} + \begin{pmatrix} \mathbf{J}_b^T \mathbf{F}_{ex} \\ \mathbf{J}_{m1}^T \mathbf{F}_{ex1} \\ \vdots \\ \mathbf{J}_{mk}^T \mathbf{F}_{exk} \end{pmatrix}, \quad (55.56)$$

where the symbols have the following meanings:

k number of limbs

$\mathbf{x}_b \in \mathbb{R}^6$: position/orientation of the base

$\boldsymbol{\phi} = (\boldsymbol{\phi}_1^T, \dots, \boldsymbol{\phi}_k^T)^T \in \mathbb{R}^n$: articulated joint angles

$\mathbf{x}_{ex} = (\mathbf{x}_{ex1}^T, \dots, \mathbf{x}_{exk}^T)^T \in \mathbb{R}^{6k}$: position/orientation of the end points

$\mathbf{F}_b \in \mathbb{R}^6$: forces/moments directly apply on the base

$\boldsymbol{\tau} = (\boldsymbol{\tau}_1^T, \dots, \boldsymbol{\tau}_k^T)^T \in \mathbb{R}^n$: joint articulated torque

$\mathbf{F}_{ex} = (\mathbf{F}_{ex1}^T, \dots, \mathbf{F}_{exk}^T)^T \in \mathbb{R}^{6k}$: external forces/moments on the end points.

Note that for Fig. 55.29, $\mathbf{F}_{exi} = [\mathbf{f}_{wi}^T, \mathbf{n}_{wi}^T]^T$.

Comparing the above equations with (55.1), no difference is observed in the mathematical structure. The gravity force on the vehicle main body and the configuration-dependent gravity terms of the articulated bodies are included in \mathbf{c}_b and \mathbf{c}_{mi} , respectively. In practice, however, one substantial difference is the existence of ground contact forces/moments at the end point of each limb. Unlike floating target capture discussed in Sect. 55.3.10, the contact is not considered impulsive, but instead continues for a nonnegligible period of time. In such cases, a well-accepted approach is to explicitly evaluate the contact forces/moments \mathbf{F}_{ex} , according to the virtual penetration of the end point into the collided object or the ground surface [55.79].

In cases in which each limb has a wheel on its end terminal, rather than the point penetration model, a wheel traction model will be adopted to evaluate \mathbf{F}_{ex} . For planetary exploration missions, rovers (mobile robots) are expected to travel over natural rough terrain. A number of studies have examined the modeling of tire traction forces on loose soil, called *regolith* (where there is no organic component) [55.84–98]. Particularly, these studies investigate the soil mechanics called *terramechanics* to understand the tractive forces generated by wheels.

In the following subsection, models for wheel traction mechanics are summarized.

55.3.13 Wheel Traction Mechanics

Terramechanics is the study of soil properties, specifically the interaction of wheeled, legged, or tracked vehicles and various surfaces. For the modeling of the wheel traction forces and the analysis of the vehicle mobility, textbooks written by *Bekker* [55.29, 30] and *Wong* [55.99] are good references. Although these books were written in the 1960s and 1970s, basic formulae from these books are frequently cited by researchers even today [55.88]. In this subsection, the models for a rigid wheel on loose soil are summarized.

Slip Ratio and Slip Angle

Slips are generally observed when a rover travels on loose soil. In particular, slips in the lateral direction are observed during steering or slope-traversing maneuvers.

The slip in the longitudinal direction is measured by slip ratio s , which is defined as a function of the longitudinal traveling velocity v_x of the wheel and the circumference velocity of the wheel $r\omega$ (r is the wheel radius and ω is the angular velocity of the wheel)

$$s = \begin{cases} \frac{r\omega - v_x}{r\omega} & \text{if } |r\omega| > |v_x| : \text{driving} \\ \frac{r\omega}{r\omega - v_x} & \text{if } |r\omega| < |v_x| : \text{braking} \end{cases}. \quad (55.57)$$

The slip ratio takes a value from -1 to 1 .

On the other hand, the slip in the lateral direction is measured by slip angle β , which is defined in terms of v_x and the lateral traveling velocity v_y as

$$\beta = \tan^{-1} \left(\frac{v_y}{v_x} \right). \quad (55.58)$$

Note that the above definitions, (55.57) and (55.58) have been traditionally used in the vehicle community as standards. However, planetary rovers in a challenging terrain, such as Spirit and Opportunity on Mars, experienced the cases in which the rovers slip backward while attempting to drive up hill, or travel faster than the wheel's circumference velocity in downhill driving. In these cases, the slip ratio can exceed the range from -1 to 1 . Also while traversing side slopes, the case may arise in which $v_y > 0$ but v_x is nearly 0 , making the definition (55.58) nearly singular. Therefore, these definitions are needed to be further discussed for the rovers in very loose terrain.

Wheel–Soil Contact Angle

Figure 55.30 depicts a schematic model of a rigid wheel contacting loose soil. In the figure, the angle from the surface normal to the point at which the wheel initially makes contact with the soil (\angle AOB) is defined as the

Fig. 55.30 Wheel contact angles

entry angle. The angle from the surface normal to the point at which the wheel departs from the soil ($\angle BOC$ in Fig. 55.30) is the exit angle. The wheel contact region on loose soil is represented from the entry angle to the exit angle.

The entry angle θ_f is geometrically described in terms of wheel sinkage h as

$$\theta_f = \cos^{-1} \left(1 - \frac{h}{r} \right). \quad (55.59)$$

The exit angle θ_r is described using the wheel sinkage ratio λ , which denotes the ratio between the forward and rear sinkage of the wheel

$$\theta_r = \cos^{-1} \left(1 - \frac{\lambda h}{r} \right). \quad (55.60)$$

The value of λ depends on the soil characteristics, the wheel surface pattern, and the slip ratio. It becomes smaller than 1.0 when the soil compaction occurs, but can be greater than 1.0 when the soil is dug up by the wheel and transported to the rear region of the wheel.

Wheel Sinkage

The amount of wheel sinkage is constituted by static and dynamic components. The static sinkage depends on the vertical load on the wheel, while the dynamic sinkage is caused by the rotation of the wheel.

According to the equation formulated by Bekker [55.29], the static stress $p(h)$ generated under a flat plate, which has a sinkage h and a width b , is calculated as

$$p(h) = \left(\frac{k_c}{b} + k_\phi \right) h^n, \quad (55.61)$$

where k_c and k_ϕ are pressure-sinkage modules, and n is the sinkage exponent. Applying (55.61) to the wheel, as shown in Fig. 55.31, the static sinkage is evaluated as follows.

Fig. 55.31 Static sinkage

First, the wheel sinkage $h(\theta)$ at an arbitrary wheel angle θ is geometrically given by

$$h(\theta) = r(\cos \theta - \cos \theta_s), \quad (55.62)$$

where θ_s is the static contact angle. Then, substituting (55.62) into (55.61) yields

$$p(\theta) = r^n \left(\frac{k_c}{b} + k_\phi \right) (\cos \theta - \cos \theta_s)^n. \quad (55.63)$$

The wheel eventually sinks into the soil until the stress from the soil balances the vertical load W on the wheel.

$$\begin{aligned} W &= \int_{-\theta_s}^{\theta_s} p(\theta) b r \cos \theta d\theta \\ &= r^{n+1} (k_c + k_\phi b) \int_{-\theta_s}^{\theta_s} (\cos \theta - \cos \theta_s)^n \cos \theta d\theta. \end{aligned} \quad (55.64)$$

Using this equation, the static contact angle θ_s is evaluated for the given W . In practice, (55.64) does not yield a closed form solution for θ_s , although θ_s can be evaluated numerically.

Finally, the static sinkage h_s is obtained by substituting θ_s into the following equation

$$h_s = r(1 - \cos \theta_s). \quad (55.65)$$

However, as illustrated in Fig. 55.32, the dynamic sinkage becomes a complicated function depending on the slip ratio of the wheel, the wheel surface pattern, and the soil characteristics. Although it is difficult to obtain an analytical form for the dynamic sinkage, it is again possible to evaluate the dynamic sinkage numerically, using the condition $W = F_z$, where F_z is the normal force given by (55.76), which will be presented

Fig. 55.32 Dynamic sinkage

later herein. The force F_z increases with the wheel sinkage because the area of the contact patch increases accordingly.

Stress Distribution Under the Wheel

Based on terramechanics models, the stress distribution under the rotating wheel can be modeled as shown in Fig. 55.33.

The normal stress $\sigma(\theta)$ is determined by the following equation [55.87, 88]

$$\sigma(\theta) = r^n \left(\frac{k_c}{b} + k_\phi \right) (\cos \theta - \cos \theta_f)^n \quad \text{for } \theta_m \leq \theta < \theta_f,$$

$$\sigma(\theta) = r^n \left(\frac{k_c}{b} + k_\phi \right) \left\{ \cos \left[\theta_f - \frac{\theta - \theta_r}{\theta_m - \theta_r} (\theta_f - \theta_m) \right] - \cos \theta_f \right\}^n \quad \text{for } \theta_r < \theta \leq \theta_m.$$

(55.66)

Fig. 55.33 Stress distribution model under a wheel

Note that the above equations are based on Bekker's formula, as given in (55.61), and they become equivalent to the Wong-Reece model for normal stress [55.100] when $n = 1$. Also note that by linearizing this distribution, Iagnemma et al. [55.84, 88] developed a Kalman-filter-based method to estimate the soil parameters.

The term θ_m is the specific wheel angle at which the normal stress is maximized

$$\theta_m = (a_0 + a_1 s) \theta_f, \quad (55.67)$$

where a_0 and a_1 are parameters that depend on the wheel-soil interaction. Their values are generally assumed to be $a_0 \approx 0.4$ and $0 \leq a_1 \leq 0.3$ [55.100].

The maximum terrain shear force is a function of the terrain cohesion c and internal friction angle ϕ , and can be computed from Coulomb's equation

$$\tau_{\max}(\theta) = c + \sigma_{\max}(\theta) \tan \phi. \quad (55.68)$$

Based on the above equation, the shear stresses under the rotating wheel, $\tau_x(\theta)$ and $\tau_y(\theta)$, are written as follows [55.101]

$$\tau_x(\theta) = [c + \sigma(\theta) \tan \phi] \left(1 - e^{-j_x(\theta)/k_x} \right), \quad (55.69)$$

$$\tau_y(\theta) = [c + \sigma(\theta) \tan \phi] \left(1 - e^{-j_y(\theta)/k_y} \right), \quad (55.70)$$

where k_x and k_y are the shear deformation moduli in each direction. In addition, j_x and j_y , which are the soil deformations in each direction, can be formulated as a function of the wheel angle θ with the slip ratio and the slip angle, respectively [55.89, 100]

$$j_x(\theta) = r[\theta_f - \theta - (1-s)(\sin \theta_f - \sin \theta)], \quad (55.71)$$

$$j_y(\theta) = r(1-s)(\theta_f - \theta) \tan \beta. \quad (55.72)$$

Drawbar Pull: F_x

Using the normal stress $\sigma(\theta)$ and the shear stress in the x direction $\tau_x(\theta)$, the drawbar pull F_x , which is the net traction force exerted from the soil to the wheel, is calculated as the integral from the entry angle θ_f to the exit angle θ_r [55.100]

$$F_x = rb \int_{\theta_r}^{\theta_f} [\tau_x(\theta) \cos \theta - \sigma(\theta) \sin \theta] d\theta. \quad (55.73)$$

Side Force: F_y

The side force F_y appears in the lateral direction of the wheel when the vehicle makes steering maneuvers or traverses a side slope. The side force is decomposed into two components [55.89]

$$F_y = F_u + F_s,$$

where F_u is the force produced by the shear stress in the y direction $\tau_y(\theta)$ underneath the wheel and F_s is the reaction force generated by the bulldozing phenomenon on a side face of the wheel. The above equation can be rewritten as

$$F_y = \int_{\theta_r}^{\theta_f} \left\{ \underbrace{rb\tau_y(\theta)}_{F_u} + \underbrace{R_b[r - h(\theta)\cos\theta]}_{F_s} \right\} d\theta. \quad (55.74)$$

Here, *Hegedus's bulldozing resistance estimation* [55.102] is employed to evaluate the side face force F_s . As shown in Fig. 55.34, a bulldozing resistance R_b is generated on a unit width blade when the blade moves toward the soil. According to Hegedus's theory, the bulldozed area is defined by a destructive phase that is modeled by a planar surface. In the case of a horizontally placed wheel, the angle of approach α' should be zero; R_b can then be calculated as a function of wheel sinkage $h(\theta)$

$$R_b(h) = D_1 \left[ch(\theta) + D_2 \frac{\rho_d h^2(\theta)}{2} \right], \quad (55.75)$$

where

$$D_1(X_c, \phi) = \cot X_c + \tan(X_c + \phi),$$

$$D_2(X_c, \phi) = \cot X_c + \frac{\cot^2 X_c}{\cot \phi}.$$

In the above equations, ρ_d denotes the soil density. Based on *Bekker's* theory [55.29], the destructive angle X_c can be approximated as

$$X_c = 45^\circ - \frac{\phi}{2}.$$

Normal Force: F_z

The normal force F_z is obtained in the same manner as for the (55.73) [55.100]

$$F_z = rb \int_{\theta_r}^{\theta_f} [\tau_x(\theta) \sin \theta + \sigma(\theta) \cos \theta] d\theta, \quad (55.76)$$

which should balance the normal load of the wheel in a static condition.

Fig. 55.34 Estimation model of the bulldozing resistance

Motion dynamics simulation for a vehicle traveling over loose soil can be performed by plugging the forces F_x , F_y , and F_z obtained from the above equations into the equation of motion (55.5).

A better understanding of the soil–wheel contact and traction mechanics is important in order to improve the navigation and control behavior of exploration rovers, in terms of minimization of wheel slippage, for example. Reducing the wheel slippage will increase the power efficiency of surface locomotion, decrease the errors in path tracking maneuvers, and decrease the risks of wheel spinning and sinking, which can cause immobilization of the vehicle.

One key in realizing such advanced control of slippage minimization is determining how to properly estimate the slip ratios and slip angles in real time using on-board sensors. The slip ratio is determined by the ratio between the wheel spinning velocity and the traveling velocity of the vehicle, but proper sensing of the velocity of the vehicle is usually difficult. One simple solution is to use a free wheel specialized for traveling velocity measurement. Another solution is to employ inertial sensors, which are however usually subject to noise and drift.

An alternative, but promising possibility is visual odometry, which is based on optical flow or feature tracking in the sequence of optical images. Actually, this technique has been applied to the Mars exploration rovers, Spirit, and Opportunity, in their long range navigation, and verified to be very useful. Particularly, the algorithm based on feature detection and tracking using stereo pair of cameras provides reliable results with good accuracy for the estimation of driving distance as well as the wheel slippage [55.28].

55.4 Future Directions of Orbital and Surface Robotic Systems

55.4.1 Robotic Maintenance and Service Missions

For many years, we have sent satellites and other systems into space without caring too much about what might happen at the end of their life cycle. There has been recently awareness about the dramatic increase of space debris and the danger of a fatal chain reaction increased in collisions. Generally speaking, space debris removal may become a prerequisite for future space-flight. Space systems above approx. 600 km flight path altitude are not currently accessible to astronauts by means of present transport systems and therefore are excluded from any kind of human removal, repair, or maintenance.

In contrast, satellites equipped with robotic arms or humanoid robonauts may be remotely controlled or only supervised from Earth in any orbit including the geostationary one. In the future, they should be able to support astronauts during routine and maintenance work on space stations, capture uncontrollably tumbling satellites, prolong their life-time by repair or refuel, deorbit or relocate them if necessary. Efficient telerobotic and telepresence technologies allow us to select flexibly the appropriate level of robot autonomy within *shared autonomy* frameworks between ground operator and space robot.

Telepresence technologies as mentioned above make sure that by real-time feedback of stereo images and force/torque information, the operator on the ground gets the feeling as though he was actually working at the remote site. High-quality telepresence requires low round-trip communication time delays. The challenge here is twofold: (a) to provide the mentioned technically feasible communication infrastructure, and (b) to apply the mentioned optimized delay-compensating telepresence technologies which yield satisfactory haptic feedback up to 650 ms delay. For large robots mounted on a carrier satellite, their dynamic interactions, including the physical contacts when grasping a target, have to be mastered (Sect. 55.3). Autonomous skills are needed for supporting a human ground operator in performing the risky task of grasping and stabilizing noncooperative tumbling targets (satellite or space debris).

Due to the high cost of space validation missions, simulation capabilities are crucial for the development and verification of on-orbit servicing systems. This applies both for the required hardware simulation facilities including sensors and illumination effects as well as for dynamics modeling techniques

and software tools. Various hardware simulators using industrial robots for simulation of chaser and target satellite motion and the dynamic interaction with the space-robot have been built up not only in DLR (Fig. 55.35).

Robotic maintenance and service missions for space infrastructure have been a long-term dream in the space robotics community since their conceptual designs were first published in ARAMIS report in the early 1980s (Fig. 55.1) [55.1].

ROTEX, ETS-VII, Ranger, and ASTRO that were introduced in the earlier section are technological developments toward this goal, but robotic maintenance and service missions have not become routinely operational yet (A good comparative study of orbital robotic missions is provided by [55.103]). The Hubble space telescope (HST) is a huge space telescope which has the capability to be serviced in orbit, but it has been visited by Space Shuttle and serviced (components exchanged and trouble fixed) only by human EVA. After the COLUMBIA accident in 2003, NASA seriously considered the possibility of robotic maintenance of the HST, investigating available technologies and selecting a prime contractor of the mission development. Figure 55.36 depicts one possible configuration for the robotic rescue mission. Ultimately, it was decided to perform this last servicing mission with human astronauts. Maintenance of the HST involves tasks that are too complicated to be done by a robot, because the HST itself was designed for human-based maintenance and not specifically designed for robots.

Robonaut, which is described in the following subsection, is therefore considered as an interesting option to be capable in conducting practical maintenance and service missions, due to its compatibility and similar level of dexterity with human astronauts.

Fig. 55.35 OOS-SIM, a hardware-in-the-loop simulator in DLR

Fig. 55.36 A conceptual drawing for robotic rescue of Hubble space telescope

55.4.2 Robonaut and JUSTIN

Robonaut is a humanoid robot designed by the Robot Systems Technology Branch at NASA Johnson Space Center in a collaborative effort with DARPA. The Robonaut project seeks to develop and demonstrate a robotic system that can function as an [EVA](#) astronaut equivalent. Robonaut jumps generations ahead by eliminating the robotic scars (e.g., special robotic grapples and targets), but it still keeps the human operator in the control loop through its telepresence control system. Robonaut is designed to be used for [EVA](#) tasks (extra-vehicular activities or space walks), i.e., those which were not specifically designed for robots.

A key challenge is to build machines that can help humans work and explore in space. Working side by side with humans, or going where the risks are too great for people, machines like Robonaut will expand capabilities for construction and discovery. Over the past five decades, space flight hardware has been designed for human servicing. Space walks are planned for most of the assembly missions for the [ISS](#), and they are a key contingency for resolving on-orbit failures. To maintain compatibility with existing [EVA](#) tools and equipments,

a humanoid shape and an assumed level of human performance (at least a human in a space suit) are required for this robotic surrogate.

The manipulator and dexterous hand have been developed with a substantial investment in mechatronics design. The arm structure has embedded avionics elements within each link, reducing cabling and noise interference. Robonaut has been designed based on a biologically inspired approach. For example, it uses a chordate neurological system in data management, bringing all feedback to a central nervous system, where even low-level servo control is performed. Such a biologically inspired approach is extended to left-right computational symmetry, sensor and power duality and kinematical redundancy, enabling learning and optimization in mechanical, electrical and software forms.

Robonaut has a broad mix of sensors including thermal, position, tactile, force and torque instrumentation, with over 150 sensors per arm. The control system for Robonaut includes an onboard, real-time CPU with miniature data acquisition and power management. Off-board guidance is delivered with human supervision using a telepresence control station with human tracking.

Robonaut 2 (Fig. 55.37), the latest generation of the Robonaut family, launched to the [ISS](#) aboard Space Shuttle Discovery on the STS-133 mission in February 2011. It is the first humanoid robot in space, and although its initial job is demonstrating its capabilities inside the space station, the goal is that through upgrades and advancements it will one day venture outside the station to help spacewalkers make repairs or additions to the station. Robonaut 2 is a dexterous, anthropomorphic robotic torso that has significant technical improvements over its predecessor to make it a far more valuable tool for astronauts. Upgrades include: increased force sensing, greater range of motion, higher bandwidth, and improved dexterity. Robonaut 2's integrated mechatronic design results in a more compact and robust distributed control system with a fraction of the wiring of the original Robonaut.

Fig. 55.37a–c NASA's Robonaut family: (a) Robonaut 2, (b) Zero-G Leg for surface inspection of [ISS](#), (c) Centaur with a surface mobility system

Fig. 55.38a,b Robonaut 2 onboard ISS: (a) measuring airflow, (b) shaking hands with ISS Commander Dan Burbank

Robonaut 2, also called R2, has completed many firsts during its two years on the ISS. During its initial checkout, it used American sign language to say *Hello World*. R2 illustrated its unique control system design that permits it to work directly with astronauts by shaking hands with ISS Commander Dan Burbank (Fig. 55.38). More recently, it has been using standard crew tools to measure airflow and demonstrate its ability to perform autonomous inventory scans. As part of gaining experience that will be useful once R2 starts working on the outside of the Space Station, on-board crew have successfully demonstrated teleoperation. Using a variety of sensors that track human hand, arm and neck motion, astronaut Tom Marshburn, while also on-board the station, became the first person to remotely control R2 to have it catch a free flying object inside the ISS.

One potential application of Robonaut technology is a regular monitoring and contingent maintenance work of human habitation modules of the space station. Figure 55.37b depicts such an application where Robonaut crawls on the surface of the station module by using hand rails which were originally designed for human EVA.

The application of the humanoid robot is not limited to orbital tasks. Figure 55.37c depict an idea to combine the humanoid torso on a surface mobility system, which shall be useful for robotic planetary explorations.

DLR's anthropomorphic JUSTIN is based on high-fidelity joint-torque-controlled light weight-technology and adjustable whole-body compliance in Cartesian space. JUSTIN on the mobile platform (Fig. 55.39) has actuated joints and torque controlled sensors. With JUSTIN's upper body the new delay compensating technologies have been verified using copies of JUSTIN's light weight arms as force reflecting hand-controllers up to delays of slightly more than 700 ms.

The European space agency ESA too, is pushing forward robonaut-type concepts, e.g., via testing a dexterous 4-finger-hand DEXHAND as developed in contract by DLR (Fig. 55.40) In spring 2012, the DEXHAND successfully passed the acceptance test and is delivered to ESA.

55.4.3 Aerial Platforms

There are three planetary candidates for aerial robotic systems: Venus, Mars, and Titan (a moon of Saturn) [55.104, 105]. Venus has a very dense but hot atmosphere (460°C and 65 kg m^{-3} at the surface), and so can easily float relatively heavy payloads. Mars has a very thin and cold atmosphere (somewhat variable but often -100°C and 0.02 kg m^{-3}). Titan has an atmosphere even colder than Mars ($\approx 100\text{ K}$) but about 50% denser than Earth's atmosphere. Thus very different vehicles have been envisioned for the three candidate mission targets. On Venus, buoyant devices are generally considered, especially those that can continuously or periodically rise high enough to reach moderate temperatures where conventional electronics can survive. One candidate is to use a phase-change fluid as part of the buoyant system, so that the fluid can condense in the cool upper atmosphere and be trapped in a pressure vessel, causing a loss of buoyancy and allowing the vehicle to descend, possibly all the way to the surface. After a brief stay, and before the heat flux to the interior of the device destroys all the sensitive equipment, a valve would be opened so that the phase change fluid can evaporate, increasing the buoyancy and allowing the craft to ascend to the cool upper atmosphere. After a suitable period of heat rejection into this cool zone, the process can be repeated, perhaps indefinitely. The density of the Venus atmosphere is sufficiently high that powered dirigibles can be used, so that the buoy-

ant vehicles can use propulsion and steering to reach particular locations in the atmosphere or on the surface [55.106].

In contrast, the Mars atmosphere is too thin for powered dirigibles to work (at least with the power-to-weight ratio of any current propulsion technology). Balloon aerobots could be deployed in the Mars atmosphere, and could ascend and descend, but probably could not be steered precisely to specific locations, at least not by use of a propulsion system. Polar balloons could circumnavigate either pole many times, or equatorial balloons could make one partial circuit around the planet, until they impact the *Tharsis Bulge*, a North–South string of high-altitude volcanoes that represents an essentially impenetrable barrier to any equatorial balloon having a reasonable payload. Because of the problems with *lighter-than-air* vehicles in the thin Mars atmosphere, there has been considerable study of airplanes for use in exploring Mars. Aircraft can be designed to have reasonable lift-to-drag ratios in the Mars atmosphere, so that their performance is not too different from airplanes on Earth. Most often considered are gliders that deploy directly from an aeroshell that comes in to the Mars atmosphere at hypersonic velocity, and then proceed to glide hundreds or a thousand kilometers before impact. One common mission concept is to fly down the great Valles Marineris canyon, taking high-resolution imagery and spectrometry of the walls of that canyon. Powered aircraft have also been considered, including those that land and regenerate their propellant (e.g., using solar power and atmospheric CO₂) so as to be able to make multiple flights.

On Titan, like Venus, buoyant devices are generally considered more attractive than surface vehicles (although helicopters have been proposed). Also like Venus, the atmosphere on Titan contains many obscuring particles and aerosols so that high-resolution imaging over a broad spectrum is only possible by getting close to the surface. This makes balloons or powered dirigibles very attractive. On Venus the extreme surface temperature makes it challenging to make a surface vehicle operate for any extended duration. On Titan, there is a significant risk that some sort of hydrocarbon *goo* exists on the surface that might foul any surface vehicle. Thus both Titan and Venus are considered especially attractive targets for the use of aerobots, especially in the form of powered dirigibles. Navigation of such aerobots presumably would be accomplished primarily by sensing the terrain and navigating relative to any landmarks that can be discerned. When these vehicles operate in the upper atmosphere, they can augment their position knowledge by means of sun or star

Fig. 55.39a,b DLR' JUSTIN, wheeled version (a) and legged version (b)

Fig. 55.40 DEXHAND

tracking (as referenced to the local vertical). Deeper in the atmosphere, this may not be possible. One key issue is whether direct communications to Earth are envisioned, or relay via satellite. If there is a satellite in orbit, it can provide considerable radio-navigation assistance and relatively frequent communications when the aerobot is on the side away from the Earth (both Venus and Titan spin very slowly). But a satellite relay is expensive, so the least expensive options require that the dirigible have a large high-gain antenna (usually presumed to be inside the gas bag). Radio-based servo pointing at the Earth will provide precise navigation information (again along with precise measurements of local vertical). However, when the aerobot goes out-of-sight beyond the limb of the planet, it may spend days or weeks out of communications with the Earth. This is probably the situation calling for the highest degree of autonomy of any that have been envisioned in robotic planetary exploration of the solar system.

55.4.4 Mobility Concepts and Subsurface Platforms

For high mobility on Moon, planets, and asteroids there is still not a final answer which technology would be optimal. Although multilegged crawlers (e.g., DLR's six-legged version as shown in Fig. 55.41) seem to be the best alternative for investigating steep craters, 4-wheeled rovers may climb up and down unbelievably steep slopes. May be wheel-leg combinations as realized in JPL's ATHLETE (Fig. 55.42) or in DLR's conceptual design (Fig. 55.43) will turn out to be the optimal solution.

Precise autonomous landing based on visual data is a prerequisite for exploration, closely related to the Future Space Systems program.

DLR's main interest however aims at fast locomotion by local autonomy thus (including collision avoidance and real-time path planning) circumventing the problem of long signal delays from 3 s (Moon) to 15–30 min (Mars). Stereo cameras with field-programmable gate array (FPGA) processor chips are capable of modeling the environment in 3-D real time,

Fig. 55.41 DLR's six-legged crawler

Fig. 55.42 JPL's ATHLETE

using e.g., the so-called semiglobal matching (SGM). Thus the goal of moving up to 10 km per hour seems realizable now.

Other modes of mobility may be superior when gravity is e.g., only 10 000 times smaller than that on earth as is the case on some asteroids. e.g., for a Japanese mission Hayabusa 2 a *jumping shoe-box* is developed by DLR using just a small excentric motor that causes moderate hopping motions over a few 100 m without reaching the fairly low escape velocity.

Subsurface exploration of planetary bodies holds great promise: it is believed that a liquid-water aquifer may exist at significant depths on Mars, and perhaps an under-ice ocean on Europa and Ganymede which probably represent the best possible locations within the solar system to look for extant (as opposed to extinct) extraterrestrial life. Also, in the lunar polar *dark craters* there is some evidence of the existence of water ice or other volatiles, and perhaps there exists a layered geologic record of impacts in the Earth–Moon system in these cold-traps. Even access to a depth of a few meters holds the promise of reaching pristine scientific samples that have not been exposed to thermal cycling or ionizing radiation [55.107].

The prevailing wisdom has been that traditional sorts of drilling rigs are required to access deep underground, involving drill towers, multisegmented drill strings, large robotic systems to serve the function of a terrestrial drilling crew, and large power systems. Also, terrestrial drilling is usually done using large amounts of fluids (water, air, or mud) to flush away cuttings and to cool and lubricate the cutter. The NASA Mars Technology Program has funded contractors that demonstrated reaching 10 m of depth in a realistic setting with segmented drill strings without the use of fluids. While this is much less than needed to reach the putative liquid water, it is much more than is reachable by previous techniques [55.108].

Fig. 55.43 Modular rover concept

Other approaches have been proposed such as Moles or Inchworms that could be relatively self-contained and yet might reach great depths without the mass and complexity of a large drill tower and segmented drill string. A key issue is that it appears that the needed energy cannot be stored on-board such self-contained drills, at least if it is stored as chemical energy. This is because drilling through terrain requires that some of the chemical bonds that hold the terrain together be broken, and so if the energy of chemical bonds is used to provide that power, then a given volume of chemical energy storage can only advance some fixed ratio of its length into the terrain, where the ratio is determined by the efficiency in taking bond energies of one sort to break bonds of a different sort. Based on these considerations, it appears unlikely that a completely self-contained subsurface vehicle could advance more than perhaps a hundred times its own length. Unless nuclear power sources are considered (and they have been), this requires some sort of tether to the surface to provide a nearly unlimited source of energy. Another problem for subsurface vehicles is that rock tends to expand when it is pulverized (in

a process called *comminution*). Nonporous rock typically expands in volume by a few tens of percent when excavated, which means that fully self-contained subsurface vehicles have a severe *conservation of volume* problem. In principle the rock can be compressed back into its original volume, but this generally requires pressures much greater than the compressive strength of the original rock. The energy required to do this is much larger than the energy required to excavate the rock in the first place, and would become the dominant use of energy in an already energy-intensive effort.

As a result, it is generally assumed that any subsurface vehicle must keep some access tunnel open to the surface so that the excess volume of cuttings can be transported out. If this tunnel is available, then it seems that a means for getting power from the surface is also available, so that self-contained nuclear power is not needed. Subsurface vehicles with diameters as small as one or a few centimeters have been proposed that could potentially reach great depths within the mass and power constraints of feasible planetary robotic exploration missions.

55.5 Conclusions and Further Reading

Space robotics as a field is still in its infancy. The speed-of-light delays inherent in remote space operations makes problematic the master–slave teleoperation approach that has been very useful in the undersea and nuclear industries. Space robotics lacks the highly repetitive operations in a tightly structured environment that characterize industrial robotics. Hardware handled by space robots is very delicate and expensive. All three of these considerations have led to the fact that relatively few space robots have been flown, they have been very slow in operation, and only a small variety of tasks have been attempted. Nonetheless, the potential rewards of space robotics are great – exploring the solar system, creating vast space telescopes that may unlock the secrets of the universe, and enabling any viable space industries all seem to require major use of space robots. The scale of the solar system is not so great (a few

light-hours) that human intelligence cannot always supplement even the most remote space robot that becomes confused or stuck. Indeed, for the Moon (with only a few seconds of time delay) it seems that hazard avoidance and reliable closure of force-feedback loops is all that is required to make a highly useful robotic system. For Mars (with tens of minutes of time delay), along with hazard avoidance and force loop closure, it seems that robust anomaly detection (with modest reflexive *safing* procedures) and perhaps scientific-novelty detection are probably all that is needed. High levels of autonomy are enhancing but not enabling for work in the inner solar system, and become more and more desirable for robots that are sent farther into the outer solar system.

For further reading, the following materials are suggested [55.109–114].

56. Robotics in Agriculture and Forestry

Marcel Bergerman, John Billingsley, John Reid, Eldert van Henten

Robotics for agriculture and forestry (A&F) represents the ultimate application of one of our society's latest and most advanced innovations to its most ancient and important industries. Over the course of history, mechanization and automation increased crop output several orders of magnitude, enabling a geometric growth in population and an increase in quality of life across the globe. Rapid population growth and rising incomes in developing countries, however, require ever larger amounts of A&F output. This chapter addresses robotics for A&F in the form of case studies where robotics is being successfully applied to solve well-identified problems. With respect to plant crops, the focus is on the in-field or in-farm tasks necessary to guarantee a quality crop and, generally speaking, end at harvest time. In the livestock domain, the focus is on breeding and nurturing, exploiting, harvesting, and slaughtering and processing. The chapter is organized in four main sections. The first one explains the scope, in particular, what aspects of robotics for A&F are dealt with in the chapter. The second one discusses the challenges and opportunities associated with the application of robotics to A&F. The third section is the core of the chapter, presenting twenty case studies that showcase (mostly) mature applications of robotics in various agricultural and forestry domains. The case studies are not meant to be comprehensive but instead to give the reader a general overview of how robotics has been applied to A&F in the last 10 years. The fourth section concludes the chapter with a discussion on specific

improvements to current technology and paths to commercialization.

Robotics for agriculture and forestry represents the ultimate application of one of our society's latest and most advanced innovations to its most ancient industries. Since the dawn of civilization, agriculture and forestry (A&F for short) remain chief among humankind's most important economic activities, providing the food, feed, fiber, and fuel necessary for our survival. (In this chapter, agriculture is understood as in the Merriam-Webster definition:

the science, art, or practice of cultivating the soil, producing crops, and raising livestock and in varying degrees the preparation and marketing of the resulting products.

Therefore, the term *crop* may be used here to denote any product of an agricultural or forestry process, including grains, cereals, fruit, vegetables, nuts, trees, beef, wool, etc. Whenever necessary, we will differentiate plant from animal products appropriately.)

Over the course of history, mechanization and automation – from the manual ploughs of yore to the modern combines of today – increased crop output several orders of magnitude. This, in turn, enabled a geometric growth in population and a corresponding increase in quality of life across the globe. Rapid population growth and rising incomes in developing countries, however, require ever larger amounts of A&F output. Scientists predict that agricultural production must double to meet the demands of nine billion people in 2050 [56.1–3]. Clearly, this cannot be achieved by simply doubling the inputs (land, water, seeds, labor, etc.) because of constrained resources and environmental concerns. Therefore, the efficiency of the A&F system must increase in a sustainable and consistent manner.

According to Reid [56.4], global agricultural total factor productivity (TFP), or the output per unit of total resources used in production, must increase from the current 1.4 to 1.75 to double agricultural output by 2050. This requires significant scientific, technologic, and management advances in all of the factors that impact TFP – seeds, soil, water, fertilizers, herbicides, insecticides, crop architecture, cultural practices, automation, labor, public policy, etc. While robotics is but one of these factors, it is one with the potential to effect A&F in a broad, systemic way, and contribute significantly to meeting our future needs.

In this chapter we address the field of agricultural and forestry robotics *from the point of view of the applications it enables*, rather than from the point of view of the elementary technologies it comprises. Furthermore, we chose to present a limited number of case studies where robotics is being successfully applied to solve well-identified problems, rather than a comprehensive survey of all work reported in the literature. We believe the former is more meaningful as it showcases top-down, problem-oriented solutions (*market pull*) rather than bottom-up, technology-led ones (*technology push*). We focus on examples from the last five to ten years, as they represent work that leverages the most recent advances in sensors and computing.

We address applications of agricultural and forestry robotics in the form of twenty case studies where robotics is being successfully applied to solve well-identified problems. With respect to plant crops, the focus is on the in-field or in-farm tasks necessary to guarantee a quality crop and, generally speaking, end at harvest time, before the crop is transported to a packing plant or warehouse. In the livestock domain, the focus is on breeding and nurturing, exploiting, harvesting, and slaughtering and processing.

56.1 Section Scope

Before presenting the case studies that showcase recent advances in robotics applied to A&F, we must define the scope of the chapter, both in terms of crop production processes and robotic technologies.

A typical crop production cycle includes several processes, among them field preparation, seeding/breeding, transplanting, planting, growing, maintenance (including attaching plants to support structures, disbudding, removing leaves, pruning tree limbs and shoots, thinning blossoms and fruit, nurturing animals, etc.), exploiting/harvesting/slaughtering, sorting, and packing. In all of them, internal transport of people, machines, and produce play a role. Single-harvest crops such as lettuce must be replaced once harvested;

multiple-harvest crops such as apples, tomatoes, and roses last a year or even several years before they need to be replanted. Depending on the crop, machinery with varying levels of automation exists for some or all of these processes. In grain and cereal production, for example, farmers have access to commercial machines for tilling, seeding, transplanting, spraying, irrigating, and harvesting. In fresh fruits and vegetables, on the other hand, mechanization and automation are more prevalent at the early and late stages of the production cycle [56.5], with crop maintenance and harvest remaining for the most part manual tasks.

With respect to plant crops, this chapter's scope is limited to the in-field or in-farm tasks necessary

to guarantee a quality crop and, generally speaking, end at harvest time, before the crop is transported to a packing plant or warehouse. Of course, there are many opportunities for robotics in those latter environments, e.g., automatic sorting and grading. We exclude them from our presentation as they are currently much more the focus of automation efforts than of robotics per se. In future editions of the Handbook, we will revisit this separation as robotics advances to post-harvest tasks.

In the livestock domain, much of farming concerns the nurturing, exploitation, harvesting, and slaughtering of animals. Slaughtering extends beyond the killing of the animal to its division into marketable portions, and subsequent packing and marketing. The essential processes considered in this section pertain to land animals and birds and include:

- **Breeding and nurturing:** Livestock can range from poultry to cattle in feedlots, including pigs and other animals. Their care involves environment and behavior monitoring, plus fodder distribution.
- **Exploiting:** In many cases, products are obtained from the live animals. Sheep are shorn for wool, cows are milked, chickens lay eggs, and bees produce honey.
- **Harvesting:** Mustering and collecting *free-range* cattle, feral pigs, and other unconstrained animals.
- **Slaughtering and processing:** Cattle, poultry, pigs, other animals are killed subject to strict regulations, then divided into marketable portions.

In a future edition of the Handbook fishing should be included, since many opportunities for robotics can be imagined there.

56.2 Challenges and Opportunities

Since the end of the industrial revolution, (arguably) the three most significant impacts robotics and automation have had on agriculture and forestry are:

1. Precision agriculture, or the use of sensors to precisely control when and where to apply inputs such as fertilizers and water
2. Auto-guidance on field crop machinery, which today can drive down a field with an accuracy unattainable by human drivers
3. Machines that harvest fruits and vegetables for processing (e.g., tomato paste and orange juice).

Academic and commercial researchers are now focusing on the next wave of *sensing*, *mobility*, and *manipulation* technologies that promise to increase A&F output and productivity.

Sensing entails measuring crop temperature, humidity, pH, wetness, image, range, and other physical attributes, and combining and analyzing the data for specific purposes. One example is a camera-based system that takes pictures of an apple orchard a few weeks before harvest and produces an accurate crop yield estimate that growers can use to plan and manage the harvest operation [56.6, 7]. The utility of sensing to A&F is that it enables decision-making at a level unattainable by human sensing alone, because the latter is either inherently inaccurate or slow or both.

Mobility relates to various levels of vehicle automation that enable driverless (or driver-assistive) field coverage; the most common example is a global positioning system/global navigation satellite system (GPS/GLS)-guided combine that harvests corn with minimal intersection between passes on the field, thus

optimizing coverage and minimizing fuel consumption [56.8]. More recently, auto-guidance has started to migrate to orchard vehicles as well, albeit here other navigation sensors may be required because of poor satellite reception under thick canopies (👁 VIDEO 26, 👁 VIDEO 91). In A&F, automated vehicles equipped with the appropriate implements enable (semi-) autonomous seeding, spraying, mowing, weed removal, harvesting, and animal feeding, among other operations (👁 VIDEO 306, 👁 VIDEO 305). Mobility requires some level of sensor-based perception, provided by GPS/GNSS, inertial units, cameras, ladars, radars, etc. These sensors are not to be confused with those described in the previous paragraph, although there certainly are situations where a sensor can perform double duty of sensing for decision making and for navigation. In general, robotic mobility technology is currently less advanced than sensing.

Manipulation refers to the various operations performed directly on the crop, including pruning, thinning, harvesting, tree training, leaf probing, tree cutting, weed removal, etc. In general, this technology requires more sophisticated sensor-based perception than mobility, and in terms of field deployment is less advanced than either sensing or mobility.

Two domains that are particularly challenging for robotics research are orchard crops and crops in protected cultivation. (We use the term *orchard* liberally to include grape vineyards and orange groves, among other similar environments where crops are grown in well-defined rows.) These are highly valuable crops, potentially generating one to three orders of magnitude more revenue per acre than field crops. They are also

characterized by the need for intensive cultivation and skilled labor. Consider, for example, apple production in the US – no less than 50 to 60% of the variable costs to produce an apple is due to labor [56.9]. On top of that, labor is needed in bursts – in Washington state, in the US, up to seven times more workers are needed during the fall harvest season than during the winter pruning season. In many developed countries, labor availability for manual orchard operations is a challenge, putting significant pressure on growers to find innovative solutions to address their labor requirements. In the 2011 Tree Fruit Industry Perspective publication, industry leaders with the US Northwest Farm Credit Services say that:

[...] seasonal labor force utilized by the tree fruit industry for thinning and harvest operations will always be an issue of concern [...]. Labor shortages at various times throughout the growing season have occurred and will likely occur in the future. The perishable nature of the tree fruit mandates a strict timeliness in field operations, and the generally narrow harvest windows do not accommodate labor shortages at critical stages. [...] New technology [...] could reduce labor requirements substantially over the next five to 10 years. Specifically, such technology would include the use of platforms and mechanical-harvest methods in the orchards, and increased use of robotics [...].

Partly in response to the high labor costs and partly to increase production efficiency, the tree fruit industry is moving in the direction of highly structured planting architectures. Whereas before an apple grower had two to four hundred trees per acre, she now has 1200 apple trees per acre in a *fruit wall* configuration that is much more conducive to automation (Fig. 56.1a). This has led to the development of autonomous vehicles and tractors that drive from garage to block and traverse tree rows for hours on end, including turning from row to row,

without any human assistance [56.10]. When equipped with the appropriate implements, these robotic vehicles can mow, spray, and collect tree and crop data for inventory management; and when configured as platforms, they can carry workers pruning, thinning, training trees, and harvesting the top part of the trees, thus eliminating the inefficiencies and injuries related to ladders. In the future, manipulators mounted on such vehicles will be able to probe plants for phenotyping purposes, and automatically prune, thin, and harvest.

A protected cultivation system is a powerful instrument to produce crops (Figure 56.1b). Greenhouses protect crops from unfavorable climate conditions and pests and offer the opportunity to modify the climate to create an environment that is optimal in terms of both crop quality and quantity. A protected cultivation is an intensive production method with high investment and operational costs, therefore permitting only the production of high value fruit and vegetable crops such as tomatoes, sweet peppers and cucumbers, flowers such as roses, chrysanthemums and gerberas and many types of potted plants. In the past decades, in western societies, this type of production has been confronted with increasing size of production facilities, increasing labor costs, reduced availability of sufficiently skilled labor, health problems of the employees due to heavy and repetitive tasks, and growing competition on the national and international markets. Automation and robotics are considered to be a way to address these issues. Additionally, growing concerns with food safety call for such technology. Last but not least, more and more a precision horticulture approach is adopted in which plants are treated on an individual basis, to improve quantity and quality of crop production whilst using resources as efficiently as possible. Given the current constraints on human labor, this has led to an even stronger call for automation and robotics.

Within the context of agricultural production, in terms of production area, protected cultivation is worldwide a relatively small business. Total area in use with protected cultivation worldwide is estimated at roughly 740 000 ha [56.11]. In terms of added value, however, protected cultivation plays a much more important role. In The Netherlands at a few percent of the area available for agricultural production, horticulture produces roughly 35% of the economic return of total agricultural production. In that case production is very capital and labor intensive. On a global scale, the potential of protected cultivation is being increasingly acknowledged. Yet, technology levels still vary widely, largely based on significant differences in local conditions in terms of market, economy, resource availability, etc.

Robotics research in protected cultivation has a history of some thirty years [56.12], focused mainly on

Fig. 56.1 (a) Modern apple orchard with trees arranged to form a *fruit wall*. (b) Vine tomato in a protected cultivation environment. These new architectures open the door to robotics-based production technologies that increase efficiency and reduce labor costs

harvesting and chemical spraying operations. Robotic harvesting focused mainly on tomatoes, cucumbers, eggplants, sweet peppers, and strawberries, for which multiple examples of research prototypes have been developed [56.12] (VIDEO 304). Single examples are known of a harvesting robot for roses [56.13] and gerbera [56.14]. Spraying robots have been reviewed in detail in [56.15]. Only two robotic systems, other than for harvesting or spraying, were found in the literature: a leaf picking robot for cucumber [56.16] and a robot for bagging, thinning, and spraying in grapes [56.17]. In protected cultivation robots have not yet been developed for actions like pruning, disbudding and attaching of plants to support structures.

Challenges in livestock production are of a more practical nature. When cattle roam freely they can be difficult to find and muster. Spotting by helicopter is expensive so there is great potential for the use of unmanned aerial vehicles. The method of collecting feral pigs and native kangaroos is usually by shooting, supplying markets in Germany and Russia respectively. There could in theory be an opportunity for the application of robotics, but it is difficult to see how this could be compatible with safety. It has been suggested that cattle could be located by carrying a transmitter. Radio communication involves considerable distances, so the use of GPS/GNSS collars with transmitting systems would pose interesting power and battery problems.

56.3 Case Studies

In this section we present a variety of case studies where robotics technologies are being applied successfully to problems in the agriculture and forestry sectors. The presentation follows a somewhat loose categorization by application domain, i. e., field crops, orchard crops, protected cultivation, forestry, and livestock. The point here is to group examples that are domain-specific but allow for the discussion of those that straddle across domains. Within each domain, the case studies follow (again, loosely) the progression from sensing to mobility to manipulation.

56.3.1 Optimized Coverage for Arable Farming

Agricultural researchers and practitioners have long-desired to have the capability to follow well-defined traffic lanes with common-width equipment systems to minimize soil compaction effects on plant growth [56.18]. The advent of automation and control technology (e.g., GNSS, automatic steering) eliminated the need for complex processes to define the controlled-traffic lanes by making it possible for agricultural machine systems to follow precise paths spatially and temporally.

With the rapid adoption of automatic guidance systems, automated path planning has great potential to further optimize field operations. Field operations should be done in a manner that minimizes time and travel over field surfaces and is coordinated with specific field operations, machine characteristics, and topographical features of arable lands. To reach this goal, *Jin and Tang* [56.19] proposed an optimal coverage path planning (OCP) algorithm where coverage is represented by a geometric model. To determine the full coverage pattern of a given field by using boustrophedon paths, it is necessary to know whether and how to decompose a field into sub-regions and how to determine the travel direction within each sub-region. The search mechanism is guided by a customized cost function resulting from the analysis of different headland turning types and implemented with a divide-and-conquer strategy. The complexity of the algorithm is $O(n^3 \log(n^3))$ for a field with n edges. In order to reduce the total turning cost, the number of turns needed to be minimized. Besides, turns with relatively high operational costs needed to be avoided. Fields of irregular shapes had inefficiencies related to headland turns when headlands were at an angle to the machine. Two-dimensional field examples with complexity ranging from a sim-

Fig. 56.2 Results obtained with the optimal coverage path planning algorithm for two-dimensional (2-D) terrains; the inner polygons indicate non-traversable obstacles

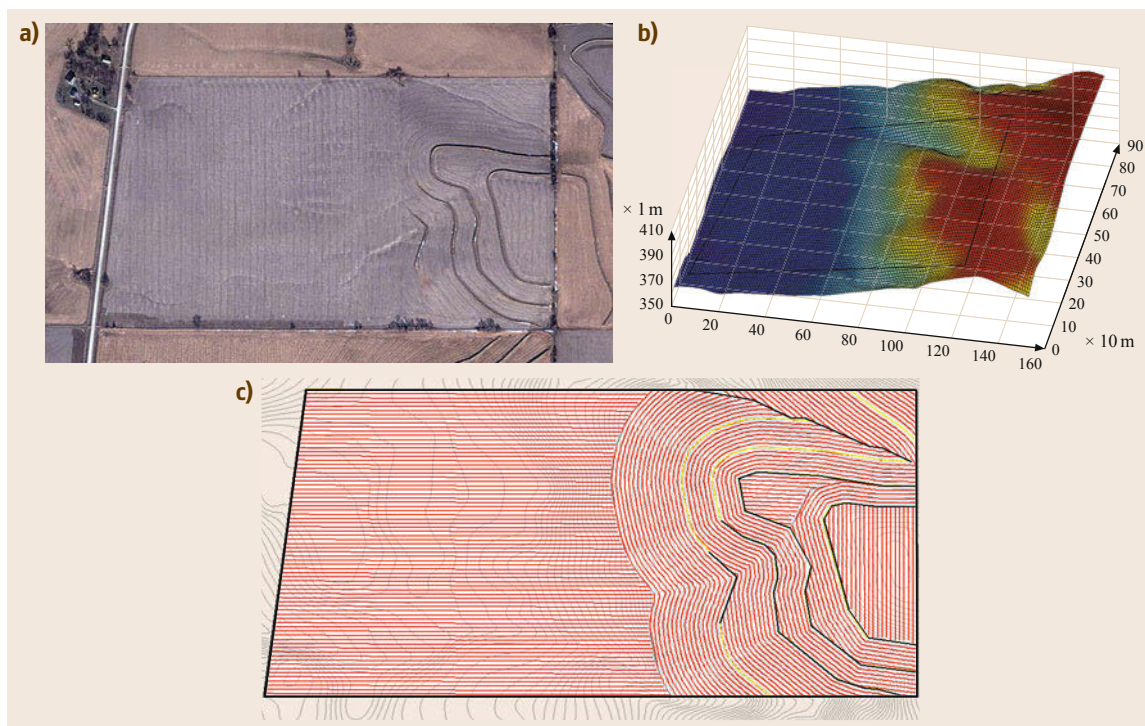

Fig. 56.3a–c Results obtained with the optimal coverage path planning algorithm for a 3-D terrain with terraces and valleys. (a) Aerial image. (b) Topographic map. (c) Optimal coverage path

ple convex shape to an irregular polygonal shape that has multiple obstacles within its interior were tested with the OCPP algorithm (Fig. 56.2). The results show that, in the most extreme two-dimensional cases, OCPP saved up to 16% in the number of turns and 15% in headland turning cost. There were no cases where OCPP outputted solutions worse than those adopted by farmers.

When optimizing coverage path over three-dimensional (3-D) terrains, more factors need to be considered, including headland turning cost, soil erosion cost, and skipped area cost. Jin and Tang developed an analytical 3-D terrain model with B-splines; and analyzed different categories of coverage costs on 3-D terrains and developed methods to quantify soil erosion cost and curving path cost corresponding to a particular coverage solution. Similar to the 2-D coverage path optimization, terrain decomposition and classification methods are used to divide a field into sub-regions with similar field attributes and comparatively smooth boundaries. The divide-and-conquer strategy was also applied in the 3-D terrain coverage planning. The most appropriate path direction of each region was the one that achieved the minimum coverage cost. A *seed curve* searching algorithm was successfully developed and applied to several practical farm fields with various topographic

features (Fig. 56.3). The 3-D planning algorithm has shown its superiority on 3-D terrain fields compared with the 2-D planner. On the tested fields, on average the 3-D version saved 10.3% on headland turning cost, 24.7% on soil erosion cost, 81.2% on skipped area cost, and 22.0% on the weighted sum of these costs, where their corresponding weights were 1, 1, and 0.5, respectively. In one of the regions, in particular, the 3-D planning algorithm generated a result with only 30.5% of the soil erosion caused by the 2-D planning algorithm. It was also observed that the skipped area resulting from the sharp turning curvature in 3-D planning is generally much smaller than the skipped area between paths when projecting 2-D planning results to a 3-D surface.

56.3.2 Weed Control

Weeds compete with the production crop for light, water, and nutrients and can have a detrimental impact on crop yield if uncontrolled [56.20]. For these reasons chemical and mechanical weed control have long received attention of agricultural engineers. Compared to current methods, robotics offers the opportunity to improve this important production task in two ways: greater precision when done mechanically, and reduced

Fig. 56.4 A robot to detect and control broad-leaved dock in grassland. Weeds are detected with a texture-based algorithm using images from a color camera (A). Navigation is GPS-based (B). A diesel engine (C) provides hydraulic power for the weeding implement (D), which can be moved laterally along the rail (E)

emissions and environmental runoff when done chemically. This section describes three examples of the application of robotics to weed control; for an overview of the field see [56.20].

Broad-leaved dock is a troublesome weed in grassland. When not controlled it may reach a high density and considerably reduce grass yield. In response to a request of seventeen organic Dutch dairy farmers, a robot was constructed to detect and control broad-leaved dock in grassland [56.21] (Fig. 56.4) (VIDEO 310). It consists of a custom platform with four independently driven wheels powered by a 36 kW diesel engine. The wheels are fitted with golf cart tires that provide traction on grass with minimal impact on the sod. Reduction gears ensure high torque, allow centimeter-precision forward movement, and limit maximum speed to a safe 3 mph. Skid steering was deemed sufficiently precise

under the circumstances. Traversal of a large, featureless pasture was achieved by using real-time kinematic GPS (RTK-GPS) to follow a pre-defined path consisting of parallel segments connected by half-circle turns at the ends. Because weeds and grass are both green, a texture-based image analysis method was used to detect the former [56.22, 23]. The weeder proposed by Riesenhuber was used [56.24]. The method consists of a rod weeder driven vertically into the ground to fragment the weed's taproot.

Volunteer potatoes are the leftovers of the previous year's harvest. After a mild winter these potatoes will sprout and constitute a serious weed. They not only compete with the production crop, but also potentially carry diseases. In The Netherlands, legislation requires that they be removed annually by July 1st. This labor-intensive task naturally called for automation. As a joint effort of industry, policy makers, and scientists, a project to detect and control volunteer potato plants was initiated [56.25–27]. A proof-of-principle machine for sugar beet fields has been built and tested (Fig. 56.5). Machine vision-based detection at 100 mm² precision was combined with a micro-sprayer with five needles and a working width of 0.2 m. The accuracy of the system was ± 14 mm in the longitudinal direction and ± 7.5 mm in the transversal direction. The main error source was the variability in micro-sprayer droplet velocity that caused longitudinal errors. Still, 77% of volunteer plants with a size larger than 1200 mm² were successfully controlled at velocities up to 0.8 m s⁻¹. Within the seed line, glyphosate was applied on weed potato plants, accompanied with up to 1.0% unwanted killed sugar beet plants.

The Intelligent Autonomous Weeder (Fig. 56.6) is a four-wheel steer, four-wheel drive platform to be used for autonomous weeding operations in arable farming [56.28–30]. The platform combines dual GPS-

Fig. 56.6 The Intelligent Autonomous Weeder operates in arable farming land

based navigation with computer vision-based row following. The four wheel steering construction offers supreme maneuverability, which is not only an advantage when precise operation within the crop is considered, but also offers the opportunity of very compact head land turns.

56.3.3 High Precision Seeding

The premise behind this work is that, if an autonomous agricultural machine could accurately follow a predefined path to carry out seeding, then the same machine could drive in the field throughout the entire growing season carrying out subsequent tasks – e.g., weeding, fertilizing, spraying, etc. – without the need for repeated crop location sensing (👁️ [VIDEO 131](#)). The primary challenge is to develop centimeter-level path tracking accuracy along straight runs by the mobile agricultural machines, and even greater accuracy (1–2 cm) in agricultural tool manipulation, e.g., controlling seeding tines for seed placement.

While there are semi-automated seeding systems currently on the market, they suffer from a number of problems with major implications for environmental sustainability, productivity, and economic return:

- They are passive, i.e., unable to take action to correct the seeding tines' path.
- The seeding implements are towed by a tractor which is [GPS](#)-guided, but with insufficient accuracy (usually 40 cm); moreover, accurate path following by a tractor does not guarantee accurate seed placement by the implement.
- The tractor does not sense deviation of the seeding implement's path, causing the crop to be laid out unpredictably.

- Even when the system senses implement deviation, it does not have the ability to correct the seeding implement's path, let alone the position of the seeding tines.
- Tractors used in current systems are massive, therefore must use fixed tracks to limit ground compaction (however still causing compaction of up to 20% of arable land).
- Insufficient seeding accuracy does not permit inter-row cropping in alternating seasons – a technique that utilizes remnant nutrients in inter-row spaces, and
- Present day systems do not have fully autonomous operational capability.

Katupitiya et al. [56.31] built and delivered a system that advanced the field in the following ways (Fig. 56.7):

- An active seeder equipped with sophisticated control systems that can take corrective action against path deviations while ensuring high accuracy seeding tine position control.
- High accuracy localization of the seeder and tines achieved via precise [GPS](#), high-precision sensors, data fusion, and control software to locate/position the seeding tines. Control systems include those that micro-adjust the seeding tines with respect to the main seeder frame. This allows the seeding tine positions to follow a more accurate path than the seeder itself.
- The seeder is force-controlled and self-propelled, allowing for the size of the tractor to be greatly reduced. Smaller tractors also mean smaller wheels, so the tractor wheel width can be smaller than the inter-crop row width; hence the tractor can use the inter-row space as its wheel tracks without squashing the crop for subsequent operations.

Fig. 56.7 Precision seeding system for broad acre farming

These result in the complete elimination of ground compaction.

- The level of automation integrated into the tractor-seeder pair is such that the entire system is readily autonomous with no operator required.
- The seeder is modular, with either single or multiple units operating around the clock. A special purpose tandem, non-linear adaptive pursuit path tracking algorithm is used to control the steering of the tractor and the seeder wheels. The seeder has its wheels under force control based on the tension at the off-axle hitch point.

56.3.4 Crop Yield Estimation

One common desire of all fruit growers is knowledge of the crop yield. Accurate yield prediction helps growers improve fruit quality and reduce operating cost by making better decisions on intensity of fruit thinning and size of the harvest labor force. It benefits the packing industry as well, because managers can use estimation results to optimize packing and storage capacity.

Typically, yield estimation is performed based on historical data, weather conditions, and workers manually counting fruit in multiple sampling locations. Manually gathering samples is a time-consuming, labor-intensive, and inaccurate process, and the number of samples is usually far too small to capture the magnitude of the variation in yield across each block. Growers are searching for an automated and efficient alternative that can accurately capture spatial variation in yield.

To deal with this need, *Nuske et al.* [56.6, 7] developed a computer vision-based system to detect and count fruit. The system uses a camera rig for image acquisition, working at nighttime with controlled artificial lighting to reduce the variance of natural illumination. An autonomous vehicle is used as the support platform for automated data collection (Fig. 56.8). The system scans both sides of each row of trees or vines, detecting fruit captured within the image sequence, and then generates yield estimates.

The accuracy of the system was demonstrated by comparing its crop yield estimation with ground-truth recorded via careful and tedious manual measurements. Its end result is a yield map that closely resembles the true spatial distribution of yield, which growers can utilize to make critical production management decisions.

The yield estimation system was deployed in a number of vineyards, apple orchards, and strawberry ranches, and the results show that the system works well in a variety of crops and training structures (Figs. 56.9 and 56.10).

Fig. 56.9a–c Output of the crop yield estimation system in vineyards (a), apple orchards (c), and strawberry ranches (b)

56.3.5 Precision Irrigation

Current irrigation practice within the agricultural community often dictates over-watering crops as opposed to under-watering. This results in wasted resource, increased leaching of fertilizers, and an increase in crop disease. There are crop models that determine adequate irrigation quantities, but they are seldom used as the constant modifying of irrigation parameters is tedious and difficult.

Kohanbash et al. [56.32] used wireless sensor networks (WSN's) to monitor environmental conditions in real time and adjust irrigation parameters on the fly. WSN's can do basic set-point control where irrigation is enabled every time the soil moisture goes below a pre-defined threshold. More advanced control methods are also possible by integrating crop water use models into the system. WSN systems communicate with a central base station that can be connected to the Internet, allowing remote access for viewing crop condition and modifying irrigation settings. Having a central base sta-

Condition	Irrigations per day
Before WSN system installed (baseline)	8
With WSN system (monitoring)	4–5
With WSN system (monitoring and control)	2–3

tion also allows growers the ability to monitor and analyze the crop growing environment for trends and long-term changes.

Early results (Tab. 56.1) show water savings of up to 75%, fertilizer leaching reduced to near zero, increased crop quality, speed of crop growth increased by over 50%, and reduced occurrence of crop disease. In addition to these savings, growers can use the data from WSN systems to tailor their crop for specific markets. For example, by adjusting the irrigation set-point

value, a grower can choose between more expensive (Grade A) product, or less expensive (Grade B) product that they can sell more of.

56.3.6 Tree Fruit Production

Autonomous orchard vehicles will radically transform tree fruit production by automating maintenance operations such as mowing and spraying and augmenting workers pruning, thinning, and harvesting. From a robotics point of view, these applications can be realized with a relatively simple, yet challenging, capability: driving along one row of trees, turning at the end of the row, and entering the next one. Challenges involved include reliably sensing the trees in the presence of sloped terrain, branches, tall grass, and missing trees; localizing the vehicle in the orchard; following trajectories inside and outside the rows; and avoiding

Table 56.2 Control modes enabled by the family of autonomous orchard vehicles in Fig. 56.11, from least to most complex

	Mule mode	Scaffold mode	Pace mode
How it works	The vehicle drives along rows of trees as workers harvest fruit, placing them in bins on the vehicle	Farm workers stand on the vehicle while it self-steers in the row	The vehicle autonomously drives an entire block at a time without requiring any further interaction

Permanent infrastructure installed in orchard	None	None	None

Fig. 56.11 A family of autonomous orchard vehicles capable of driving among tree rows, based on the Toro Workman series. To keep cost low, the vehicles use only a laser rangefinder and steering and wheel encoder for perception and navigation

obstacles. Additionally, the added cost of the autonomy components should be as low as possible, to make such vehicles commercially viable.

Figure 56.11 shows a family of autonomous orchard vehicles with a common sensing and computing infrastructure that allows them to cover entire orchard blocks continuously for several hours (VIDEO 91). To keep cost low, they are not equipped with GPS/GNSS or inertial navigation systems; instead, perception and navigation is achieved with a laser rangefinder mounted on the front of the vehicle and steering and wheel encoders. Table 56.2 summarizes the three autonomous control modes in which the vehicles can operate.

From 2008 to 2012 the vehicles drove a combined 350 km in experimental and commercial orchards, vineyards, and nurseries in several US states, including many in the largest apple producer in the United States, Washington state. The longest run covered 25 km over five hours [56.10, 33]. Time trials conducted by The Pennsylvania and Washington State Universities Extension educators showed that workers onboard an autonomous orchard platform can be twice as fast as workers using ladders or on foot when working on the top portion of apple and peach trees (Fig. 56.12) [56.34].

56.3.7 Vehicle Formation Control

Multiple robotic agricultural vehicles driving in formation offer capabilities beyond those possible by a single vehicle. *Lenain et al.* [56.35] developed a control architecture that enables accurate and stable control of several robots in a given and possibly variable formation. The method is based on a path tracking framework, defining the relative robot's positions as a lateral dis-

Fig. 56.12 (a) Autonomous orchard vehicle. (b) Workers on foot harvest apples and deposit them on bins towed by the vehicle, eliminating the need for and the cost of a tractor driver. (c) In this version the vehicle is equipped with a lift platform from where workers can prune, thin, tie trees, and place pheromone dispensers up to twice as fast as workers performing the same operations on ladders. Users on the platform control the vehicle from an interface (d) that communicates with the onboard computer wirelessly

tance with respect to a given path, and the longitudinal distance along this path. Perturbations due to motion on natural environments (e.g., poor grip conditions and uneven terrain topography) are compensated with a non-linear model-based controller that includes an observer for wheel sideslip. In the formation control point of view the lateral error is no longer regulated to zero but to a desired set-point, potentially variable and accounting for other vehicle deviations. In addition, the velocity of each vehicle is controlled in order to ensure a desired curvilinear distance with respect to the others, and imposing a desired speed for one of them. Similarly to lateral dynamic, the desired distance may be defined as varying, and error may be constituted of a mix between longitudinal errors of one vehicle with respect to the other.

This approach was tested in the field with two electrical off-road robots (Fig. 56.13a). They are equipped with RTK-GPS providing an accuracy of ± 2 cm, and are able to communicate their positions among each other using wireless communications. Weighing around 500 kg each, these two-meter long vehicles are able to reach speeds of 4 m s^{-1} and climb up to 20 degrees terrain. In this example, the first vehicle has to follow the trajectory depicted in black, composed of a straight line along a 15 degree slope on grass at a speed of 2 m s^{-1} , followed by a half turn coming back on flat ground. The second vehicle must follow the first one with a desired curvilinear distance of 10 m and a desired lateral

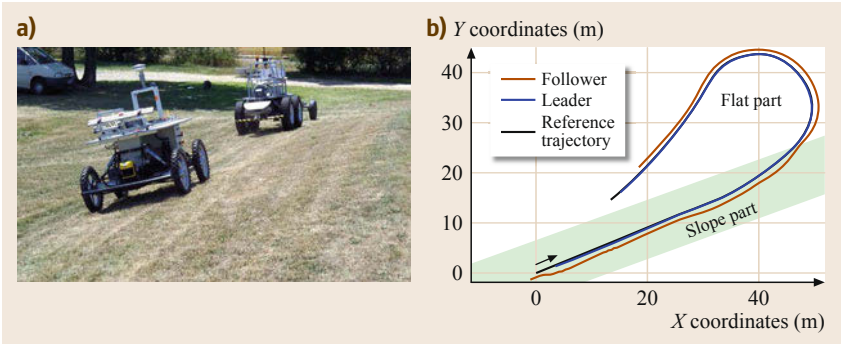

Fig. 56.13 (a) Two agricultural vehicles in formation control. (b) Reference trajectory and actual path achieved by the two vehicles

Fig. 56.14 Date tree tracking system adapted to a commercial sprayer. The system aims the sprayer nozzle toward the trees more efficiently and safely than a human operator

deviation of 1 m. The positions of the first and second vehicles are shown in blue and red dots in Fig. 56.13b, respectively. In these conditions, the accuracy of relative positioning is within ± 15 cm despite the challenging terrain conditions (low grip, uneven terrain, curved

trajectory). This work demonstrated the capability of maintaining a formation of several vehicles, compatible with the conditions encountered in agriculture, allowing to consider the introduction of multi-vehicle platoons in the field for precision agriculture.

Fig. 56.15 Calculation of the desired spray angle

56.3.8 Date Palm Tree Spraying

Dates palm tree spraying is normally done manually by a team of three workers from a platform 18 m or more above the ground. In the past, many accidents have occurred due to instability of the platform when in a lifted position. Degania Sprayers Company (Israel) developed a sprayer with a tall air cannon and a pan-tilt unit at the end to control the air flow and spray direction. This system, however, requires a worker to manually aim the spray toward the tree. Shapiro et al. [56.36] developed an automatic tree tracking system for the sprayer (Fig. 56.14).

The tracking system is based on an ultrasonic range sensor to detect the trees and a proximity sen-

sor mounted on the sprayer's wheel to measure distance traveled. A human driver is responsible for maintaining the sprayer a distance $D_2 = 3.5$ m from the trees. Knowing the average distance between trees in the row ($D_1 = 9$ m), it is possible to compute the desired spraying angle as $\theta = \tan^{-1}((D_1 - x)/D_2)$, where x is the distance traveled since the last tree (Fig. 56.15). This value is fed into a proportional–integral–derivative (PID) controller that outputs a pulse-width modulation (PWM) signal to an electrically-controlled hydraulic valve that controls the spraying angle. The authors opted to use an on/off valve driven by a PWM signal instead of a proportional valve to reduce the system cost and therefore make it more attractive to farmers. The rotation angle of the sprayer is measured by a potentiometer and used as feedback for the PID controller. When the sprayer reaches the midpoint between two trees, i.e., $x = D_1/2$, the sprayer is set to rotate toward the next tree in the row and start spraying it. The tracking algorithm is implemented on an Arduino microcontroller.

The system was built and deployed in date farms, showing good tracking results. It replaces a human worker which previously had to perform a dull task controlling the sprayer to track the trees using a joystick. A preliminary economic analysis indicates that the additional cost of the sprayer tracking system can be recovered in one harvest season.

56.3.9 Plant Probing

In large botanic experimentation fields, treatments (watering, nutrients, sunlight) that optimize certain desired aspects (growth, appearance) need to be determined. Towards this aim, experiments entailing many repetitive actions need to be conducted. For example, measurements and samples from leaves must be taken regularly and some pruning may need to be performed. For these tasks robots would be very handy, but difficulties arise from the complex structure and deformable nature of plants, which do not only change appearance through growing, but whose leaves also move on a daily and sometimes hourly basis. Even though recent advances in depth sensors, deformable object modeling, and autonomous mobile manipulation have brought this goal in reach for robotic applications [56.37, 38], many problems still exist, in particular concerning robust recognition and localization of plant parts (leaves, flowers, fruits, stems), and robot manipulation under weakly constrained conditions in natural environments.

In this context, the European project **GARNICS** (gardening with a cognitive system) aims at 3-D sensing of plant growth and building perceptual representations for learning the links to actions of a robot gardener.

Fig. 56.16 (a) Chlorophyll measurements with a robot-mounted spad meter. (b) Cutting of leaf disks with a robot-mounted, custom-designed cutting tool. Both a color camera and a ToF camera are mounted on the end-effector of the arm. (c) Close-up of probing: Chlorophyll measurements of a tobacco plant. The lightweight time-of-flight camera is seen at the top

Fig. 56.17 (a) Color image. (b) Infrared image. (c) ToF depth. (d) Segmentation. (e) Surface models. (f) Color-coded leaf confidences and extracted probing points

Plant sensing and control is addressed by combining active vision with appropriate perceptual representations, which are essential for cognitive interactions (VIDEO 95).

An application of robotized phenotyping related to this project is the accurate placing of a measurement tool on a leaf in order to either cut sample disks from the leaf, or to measure chlorophyll content. The robotic arm is equipped with a time-of-flight (TOF) camera and a measurement tool (Fig. 56.16) [56.39–41]. In this approach, image segmentation and model fitting are employed to recognize and localize single leaves from depth information. 3-D data is combined with color or

Fig.56.19a,b Cucumber leaf removal robot. (a) Robot operational in the crop. (b) End-effector (after [56.16])

infrared images and used to segment the data into surface patches, which are assumed to correspond to actual plant leaves [56.42].

In this approach, a next-best view strategy was proposed for finding a non-obstructed and frontal view of the leaf [56.41]. Initially, the robot arm is moved to a position from which a general view of the plant is obtained. The depth and infrared images acquired from this position are segmented into their composite surfaces, leaf model contours are fitted to the extracted

segments, and the validity of the fit and the graspability of the leaf are measured (Fig. 56.17). A target leaf is selected and the robot moves the camera to a closer, frontal view. The validity of the target and the graspability are re-evaluated. If the leaf is considered to be suitable for sampling based on these criteria, the probing tool is placed onto the leaf following a two-step path. If the target is not considered suitable for probing, another target leaf (from the general view) is selected and the procedure is repeated.

The method is based on several assumptions:

- i) The boundaries of leaves are visible in the infrared-intensity image
- ii) The leaf surfaces can be modeled by a basic quadratic function
- iii) Leaves of a specific plant type can be described by a common 2-D contour
- iv) Leaves are large enough to allow analysis by a ToF camera, and
- v) The leaves are static during probing.

These assumptions may be violated under certain conditions, and further research will have to be undertaken to solve the various problems originating mostly from the complex and deformable nature of plants.

56.3.10 Cucumber Harvesting

A prototype robotic harvester for cucumbers is presented in Fig. 56.18. The machine consists of a mobile platform that runs on rails (VIDEO 308). These rails are commonly used in greenhouses in The Netherlands for the purpose of internal transport, but they are also used as a hot water heating system of the greenhouse. Harvesting requires functional steps such as the detection and localization of the fruit and assessment of its ripeness. In case of the cucumber harvester, the different reflection properties in the near infra-red spectrum were exploited to detect green cucumbers in the green environment [56.43–45]. Whether the cucumber was ready for harvest was identified based on an estimation of its weight. Since cucumbers consist almost 95% of water, the weight estimation was achieved by estimating the volume of the fruits. Stereovision principles were then used to locate the fruits to be harvested in the 3-D environment. For that purpose the camera was shifted 50 mm on a linear slide and two images of the same scene were taken and processed. A Mitsubishi RV-E2 manipulator was used to steer the gripper-cutter mechanism to the fruit and transport the harvested fruit back to a storage crate. Collision-free motion planning based on the A* algorithm was used to steer the manipulator during the harvesting operation [56.44]. The cutter consisted of a suction cup on a parallel gripper

that grabbed the peduncle of the fruit. (The peduncle is a stem segment that connects the fruit to the main stem of the plant.) Then the action of a suction cup immobilized the fruit in the gripper. A special thermal cutting device was used to separate the fruit from the plant. The high temperature of the cutting device also prevented the potential transport of viruses from one plant to the other during the harvesting process. For a successful harvest this machine needed 65.2 s on average. The success rate was 74.4% [56.43].

56.3.11 Cucumber Leaf Removal

Harvesting has received considerable attention in robotics research focused on protected cultivation. Yet, this is not the only time- and labor-consuming cultivation operation. In cucumber production, amongst others, removal of old non-productive leaves in the lower regions of the plant is a time-consuming task. Figure 56.19 shows the same platform used for harvesting, but in this case hardware and software were used for removal of leaves from the plants [56.16] (VIDEO 309). In this system, the camera system is used to identify and locate the main stem of the plants. The gripper is sent to the plant and moved upwards. Leaves encountered during this upward motion are separated from the plant using the similar thermal cutting device as used for harvesting. An interesting feature of this machine is that with slight modifications of software and hardware, two greenhouse operations could be performed.

56.3.12 Rose Harvesting

In recent years a harvesting robot for roses has been developed and tested under practical circumstances in The Netherlands. The prototype is shown in Fig. 56.20. In this case, the rose plants are grown on moveable benches. Thus plants move to the robot instead of the robot moving to the plants in the greenhouse. During the harvest cycle, a camera system travels over the rose

plants and locates the roses to be harvested. Then the harvesting operation is performed with two manipulators. One manipulator grips the rose just below the flower and pulls it gently aside to generate space for the second manipulator to travel down the stem towards the point where it will cut the stem. This manipulator carries a small-sized stereovision system that is used for real-time tracking of the stem during this downwards motion. Upon arrival, the manipulator deploys a small scissor-type cutter that will cut the stem. Then, finally, the rose is pulled out and put in a storage by the first manipulator whilst the second manipulator moves out of the crop and proceeds with the next harvest cycle. Details of this system have been covered in [56.13].

56.3.13 Strawberry Harvesting

In Japan, the market of strawberries is large, as large as the market of tomatoes, cucumbers, and mandarin oranges. The potentially high-economic return of this product together with the high labor intensity of processes like harvesting, explains the long tradition of research on robotic strawberry harvesting. As shown in Fig. 56.21, the robot consists of a 4 degrees-of-freedom (DOF) cylindrical manipulator. The robot carries 3 charge-coupled device (CCD) cameras. A square LED-array is used for illumination of the scene. Two cameras provide stereo vision for detection and localization of the fruits. Once a fruit is detected, the end-effector is positioned in front of the fruit. The third camera, mounted on the end-effector, is then used to detect the peduncle, i.e., the fruit stem, and calculate its inclination. Based on this data, the orientation of the end-effector is modified with a tilt mechanism and it then approaches the fruit. A successful approach of the strawberry is detected by a reflection-type light sensor in the end-effector. Upon successful completion of this motion, the peduncle is grasped and the stem is cut with a scissor-type cutting mechanism. A suitable manipulator motion then sends the harvested strawberry to a tray. This procedure is repeated for all detected fruits at the

Fig. 56.20a,b A rose harvesting robot. (a) The robot with the rose crop on a mobile growing system. (b) The end-effector with stereo vision system and a scissors-type cutting device (courtesy Jentjens Machinetechniek BV, Veghel, The Netherlands)

Fig. 56.21 A strawberry harvesting robot (courtesy IAM-Brain, Japan)

current position of the robot. After all picking attempts are completed the full robot platform is moved 210 mm with a gantry-type transportation system running below the strawberry benches. The current prototype has achieved a picking speed of 6.3 s with a success rate of 52.6%. For more details refer to [56.46, 47].

56.3.14 Pot Handling in Nurseries and Greenhouses

Nursery and greenhouse (N&G) farms in the United States produce over two billion potted plants annually (Fig. 56.22a). During the course of production plants are moved several times – distributed onto indoor or

outdoor growing beds, repositioned to recover space as orders are filled, and collected for bulk transport. Until recently, only scarce manual labor was suitable for these jobs (Fig. 56.22b).

Harvest Automation's recently-marketed HV-100 (*Harvey*) robot automates critical N&G tasks (Fig. 56.23a). Plants are lifted and transported using a one degree-of-freedom manipulator coupled with a one degree-of-freedom gripper. The mobility system employs two differentially-controlled drive wheels balanced by a front roller.

Harvey uses a laser rangefinder to identify the containers in which plants are grown. This sensor has a horizontal field-of-view greater than 180 degrees and can detect poorly reflecting plant containers from at least 4 m – even under bright sunlight. The robot also uses the laser rangefinder to detect obstacles and robot teammates.

Four *boundary sensors*, two forward-pointing, two rear-pointing, are used to find and follow retroreflective tape that marks the edge of the bed. The tape marker performs double duty as both the robot's global reference and as part of the user interface. By positioning the boundary marker workers indicate to the robot where plants should be placed.

A user interface consisting of a dial and buttons is located on the back of the electronics box. The interface enables users to input the desired plant spacing, bed width, spacing pattern (hexagonal or rectangular) and the number of aisles the robot should instantiate.

Robust operation of the robot is enabled by a behavior-based programming scheme. Figure 56.23b illustrates *spacing*, a task that gives each plant sufficient room to grow without interfering with its neighbors. The closely packed plants in the foreground have been delivered to the growing bed and placed on the ground. Robot A identifies plant containers using the rangefinder; it selects for pick up the container farthest down field. After closing on and capturing a container with its gripper the robot will turn toward the boundary B. Nearing the tape marker the two forward boundary sensors on the robot will detect the tape and compute the relative angle between robot and tape. This enables

Fig. 56.22a,b Potted plants destined for garden stores and landscapers are grown in containers on immense nursery farms. Large amounts of stoop labor is needed to place, maintain, and retrieve these plants

Fig. 56.23 (a) HV-100 (*Harvey*) nursery and greenhouse automation robot with main components labeled: (A) laser rangefinder, (B) boundary sensor (two of four), (C) gripper, (D) emergency stop flag (pulling the flag stops the robot), (E) electronics box, with user interface components mounted on the back, and (F) passive roller to balance the robot. (b) Two robots operating as a team perform the spacing task. Robot A approaches the source plants in the foreground. Boundary B marks the edge of the bed. Robot C carries a plant toward the destination

the robot to turn and align with the tape, keeping the tape on its left side.

After acquiring the boundary marker the robot will servo along the tape as robot C is doing. When the plant destination comes within view the laser rangefinder is used to identify the next empty space in the pattern of *spaced* plants. The robot then computes an efficient path to the put-down point, moves to that position, and drops off the plant. Afterward, it turns back toward the source of plants and repeats the process. The robot uses dead reckoning to find its way to the vicinity of the source plants. Following this strategy robots can work singly or in teams of various sizes.

56.3.15 Precision Forestry

About 30% of the land mass of the earth is covered by forests. In addition to providing the raw materials for furniture, paper, clothing, and heating, forests provide habitats to diverse animal species and form the source of livelihood for many different human settlements. In 2012, in Germany alone, an estimated 1.3 million jobs in the wood processing industry generated a revenue of more than 180 billion euros. To explore forests in an environmentally-friendly but still economical way is thus a major issue. Robotics is currently being used to preserve the forest and secure the jobs in forestry and related industries.

Today, work in forests is already highly mechanized, and in the last decade, mobile robotics know-how combined with new virtual reality and remote sensing techniques paved the way for a new *robotics view* onto work machines in the forest. Wood harvesters (Fig. 56.24) and forwarders, advanced work machines for log cutting and transport, are currently a major aim of automation efforts [56.45, 48, 49]. Based on the in-

Fig. 56.24 (a) A simulated wood harvester equipped with simulated laser scanners in a virtual testbed used for algorithm development and evaluation. (b) The physical harvester in the woods, equipped with laser scanners mounted to the right and left door of the cabin

sight that accurate machine localization cannot solely be based on **GPS**, mobile robotics capabilities for localization and navigation have been introduced. Measured **GPS** errors of up to 50 m due to signal absorption in the canopy and to multi-path effects make **GPS** practically useless for precise localization and navigation. In

Fig. 56.25 (a) Top-down view of the machine, particles (gray dots), trees from global tree map (light blue dots) and trees from local tree map (dark blue dots). (b) Particles accumulate near the left edge of the cabin of the forest machine and indicate the newly calculated position in comparison to the GPS-based position (white rectangle below the harvester). (c) A semantic world model turned into a virtual forest.

the *VisualGPS* approach, the GPS position only serves as a starting point for a combined Kalman filter and Monte Carlo localization algorithm based on optical range measurements by laser scanners (VIDEO 96). The approach yields a machine position with an accuracy of 0.5 m and thus provides a sound basis for the development of navigation and (semi-) autonomous logging procedures [56.50, 51].

Practical experiments show that map building based on simultaneous localization and mapping (SLAM) techniques [56.52] are not very applicable in these environments, because the resulting errors in the map are not bounded and thus are not well-suited for large area operation and for a matching against parcel borders. Instead, the highly accurate position estimation from *VisualGPS* builds on a previously generated map of single trees. A multi-sensor fusion approach helps to build this map based on airborne and satellite imagery in multiple spectral ranges as well as on airborne laser scanning. The multispectral imagery data provides the basis for the tree species determination which is solved as an advanced pattern classification problem [56.53]. The next step, single tree delineation, is based on airborne imagery in combination with 3-D surface data from the laser scans. A modified watershed algorithm [56.54] delineates the tree crowns. From the tree crowns' sizes and species information, the geo-referenced stem position and even the trees' diameters can be deduced. This not only allows for generating a global, geo-referenced tree map, but is also sufficient for generating a semantic world model, the *virtual forest* (Fig. 56.25).

Each work machine in the forest also builds local maps of visible trees using machine-mounted laser scanners and a compass. For localization purposes, these local maps are matched against the previously generated global map of trees by means of a particle filter. For a moving machine, the prediction step is carried out by a Kalman filter [56.50, 51].

Figure 56.25 shows the two important results of the global map building process. The figures on the

left show just the tree map with the white noise in the upper image denoting the particles representing potential poses for the Monte Carlo localization process. In the lower image, the particles have converged against the machine's correct position. The right image gives an impression of the *virtual forest* generated from the same data that was used for the tree map. This *virtual forest* is used to visualize the deduced information (e.g., tree species, tree height, crown shape and size, etc.) in a high-end virtual reality representation. This approach follows a general trend in robotic applications for natural or space environments: the development of virtual testbeds for world model information visualization in an intuitively comprehensible manner. Advanced virtual testbeds then provide the simulation capabilities to develop and test the robotic application against the virtual world in order to save time and costs [56.55].

The developed laser rangefinder-based *VisualGPS* algorithms are being enhanced by optical stereo image recognition capabilities and are being ported to mobile platforms like the Seekur Jr. This is due to the fact that the work that started as an automation effort for work machines in the forest has recently turned into an environment monitoring project which aids the forester to inspect, protect, and attend to the forest with increased efficiency and effectiveness.

56.3.16 Semi-Automation of Forwarder Crane

In cut-to-length harvesting, which is the predominant tree harvesting method in Europe, delimbed and bucked timber is collected from the forest to the roadside by a forwarder. For an operator of such a machine, a large part of the work cycle consists of maneuvering the onboard hydraulic crane (Fig. 56.26). The operator controls the links individually using two joysticks. The redundant kinematic design is necessary for dexterity and the large active workspace of the machine, but it

Fig. 56.26 (a) Valmet 830 forwarder with redundant kinematic design of the hydraulic crane. (b) The operator uses two joysticks to control each link individually

also makes the crane control difficult to learn and to perform in an efficient way.

Considering the technological progress and capabilities of today's forestry machines, the current manual control approach creates bottlenecks in the forwarding process. Semi-automation of these operations would thus be beneficial for productivity. Automation of some repetitive motions is also desired in order to support the operator and to reduce the physical and cognitive workload.

To this end, a small-scale hydraulic forwarder crane has been installed in a laboratory environment [56.56]. The crane is equipped with position and pressure sensors, as well as with electronics and software for rapid prototyping of automated control strategies. The same equipment has been installed on a commercial Valmet 830 forwarder by Komatsu Forest for field testing.

Using these platforms, new feedback control methods and trajectory planning procedures have been developed to construct and implement time-efficient motions [56.57]. For a given geometric path, the speed and relative use of the different crane links along this path can be shaped to achieve motions with optimal performance within the limitations of the machine. Velocity constraints for the individual joints are particularly restrictive in hydraulic manipulators.

In [56.58], trajectories planned with this approach are compared with recorded motions by professional human operators with respect to execution time. Results show that the performance can be improved significantly by path-constrained replanning of human-operated motions (Fig. 56.27). Additional replanning of the geometrical path, along with efficient velocity profiles along the path, can further improve the time efficiency of the crane motions.

Tracking the trajectories with feedback control requires sensors for measuring the joint positions. Installation of such sensors may not be desired due to high

costs or durability problems in the rough outdoor environment. Using the approach in [56.59], motions can be found that are robust to uncertainties in initial conditions and therefore possible to perform in open loop. The end effector position along the trajectory can also be estimated using an observer and signals available from pressure sensors. Such design can be a more convenient solution in the harsh conditions of the forest.

The introduction of new tasks or new ways to perform tasks means new challenges for human-machine interaction (HMI). Semi-autonomous operation requires the automated parts to be well integrated with the manual work. In order to facilitate cooperation in manipulator control between the human and computer, the work distribution and work transitions between them is important. *Hansson and Servin* [56.60] describes an implementation of shared and traded control for this setup. The results from user tests show that semi-autonomous operation reduces the workload and shows significant potential to improve the productivity of inexperienced operators.

A reliable framework of sensors and low-level control, along with efficient motion planning strategies, allows for development of more advanced interaction technologies. One such possible future scenario is teleoperation, that presents several advantages to both machine owners and operators. Firstly, it opens up for redesign of the machine with removal of the cabin which saves weight and cost. Secondly, the working environment is improved with reduction of the noise and vibration levels. A virtual environment-based system for teleoperation of a forwarder crane was demonstrated in [56.61]; follow-up work is investigating how a virtual environment can be a useful tool for presenting feedback to the operator in different scenarios. This method does however require environment reconstruction to locate logs and potential obstacles, both of which are considered in [56.62].

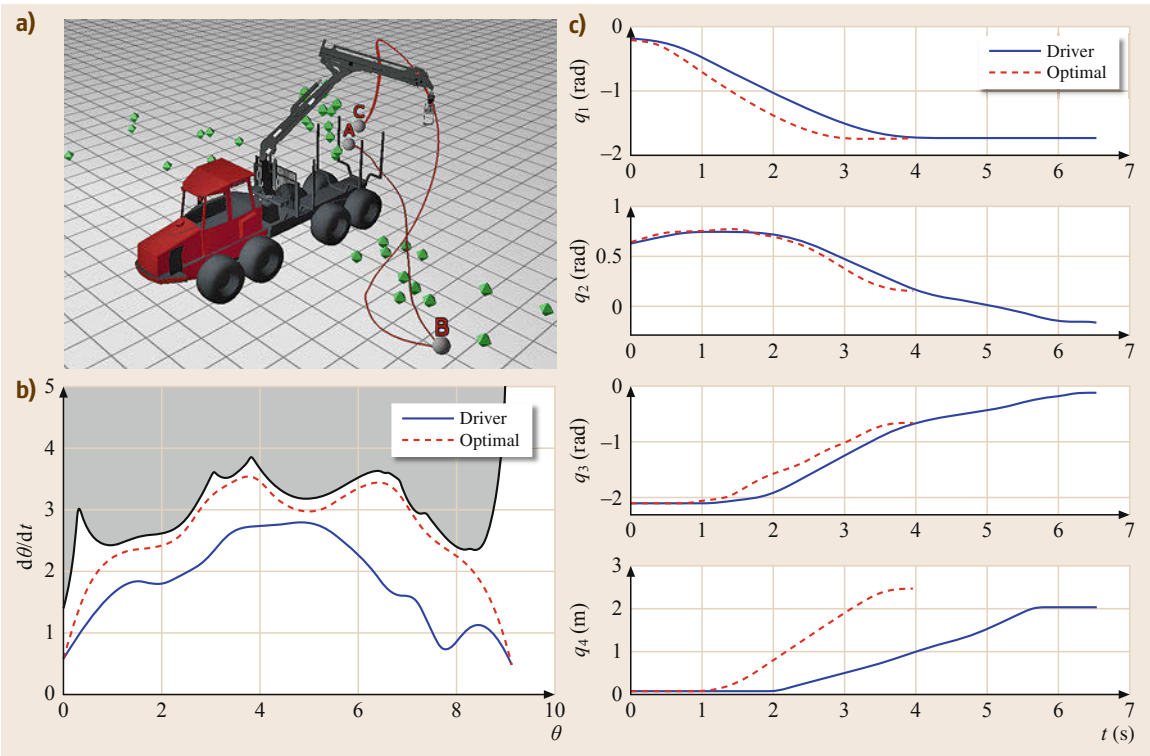

Fig.56.27a–c Path-constrained replanning of human-operated motions. **(a)** Example of two crane motions performed by a human operator: from the load bunk to the logs (A–B) and back (B–C). **(b)** Velocity profiles for the distance θ along the path A–B. A different distribution of the work between the joints allows for a higher velocity along the same path. The gray area indicates velocity constraints not to be violated. **(c)** The resulting evolution of joint coordinates with respect to time. The motion with a time-efficient velocity profile is clearly faster than the one of the driver

56.3.17 Livestock Breeding and Nurturing

In some cases animal breeding is a proactive process, such as in hatcheries where optimum conditions must be managed. In others nature is allowed to take its course. Sometimes intervention may be needed in the

birthing process, but in the Australian outback cattle must take their chances. Nevertheless the newborn must be marked with transponder tags under the national live-stock identification scheme, NLIS [56.63].

Other species such as kangaroos, feral pigs, wild camels and horses can breed and run wild until harvested or culled. When creatures are confined, tasks

Fig. 56.28 Lely Juno robot

Fig. 56.29 Lely Vector feeder

include environmental monitoring and control, feeding, cleaning and growth monitoring.

A Dutch company, Lely [56.64], is active in marketing products that have a strong robotic element. When cattle are located in stalls, the Juno [56.65] patrols the laneway at the side of the pen, pushing fodder towards the rails to put it in reach of the feeding cattle (Fig. 56.28).

The Vector [56.66] goes even further. A mobile robot carrying a hopper, it navigates automatically between the barn that holds the feed and the stalls where the cattle are waiting (Fig. 56.29).

Other equipment in Australian feedlots estimates the weight gain of the cattle, such as a system that reads the NLIS tag of a beast at a water trough and records the weight imposed by the front legs.

In the Australian outback, similar sensing systems perform a variety of functions. Water is scarce, so watering points can be fenced, giving access only via a laneway that can be monitored. Some earlier projects [56.67] have involved species identification to control access by means of an automatically operated gate, but similar technology has valuable use in cattle production.

Again the NLIS tag is read, while a *walk over* weighing system notes the weight gain of the animal. Vision can be used to identify cows that are followed by a calf. Now automatic gates can direct these to a separate paddock for tagging the calves.

Many of the opportunities are for automation, which may be a precursor for robotics. Several projects have involved machine-vision monitoring of cattle [56.68] or of pigs in piggeries [56.69]. The weight-gain is estimated by visual means using precision cameras (Fig. 56.30). Other analyses concern behavior [56.70].

Mobile robots can be involved in sheds where chickens are bred for meat, rather than laying. A mobile robot has been proposed for moving among the poultry to monitor air quality including temperature, relative humidity and the concentrations of ammonia and dust.

Fig. 56.30 Measuring the live weight of cattle with vision

Australian honeybees must also be protected from pests, carried by bees on arriving ships. Bait boxes are deployed at ports around Australia to attract any such swarms. A remote monitoring system with camera sensing gives an early alert to the apiary officer [56.71].

56.3.18 Livestock Exploitation

Traditional farming practices milk cows twice a day; in morning and in the evening. Automatic milking parlors with robotic milking stations are being widely adopted to improve dairy productivity and convenience (Fig. 56.31). These allow the cows to self-determine when to come in for milking and feeding. In an automated milking station, teats are located and attachment

Fig. 56.31 Robot milking

Fig. 56.32 Engineers demonstrate how their pioneering sheep shearing robot works at the University of Western Australia in 1980 (courtesy National Archives of Australia: A6180, 23/9/80/1)

of milking systems is automatic. Yield is monitored and udders are automatically inspected for injury and disease. Human intervention is minimal. The Lely company is active in this area [56.72].

Once a year sheep must be shorn of their wool. In the past, the University of Western Australia developed an automatic shearing system known as the Shear Magic [56.73] (Fig. 56.32). The commercial exploitation was not a success and there seems to have been little activity in this area in recent years.

Fig. 56.33 Prototype computer vision system for scanning the egg collection belt for potential blockages

Fig. 56.34 Precision Pastoral's mustering method

Eggs must be collected from battery hens. As they are laid, they roll from the cages onto a conveyer belt. Among other robotic applications in egg production, machine vision is used to detect foreign bodies or damaged eggs [56.74] (Fig. 56.33).

56.3.19 Livestock Harvesting, Slaughtering, and Processing

The system already described for monitoring cattle that approach a waterhole is also the subject of a funded project for mustering. Cattle, selected by means of their NLIS tags, are diverted into a compound from which they can be collected for transport to a feedlot, in preparation for slaughter [56.75] (Fig. 56.34).

The vision-based system that can control access to waterholes can also be used for the collection of feral animals such as pigs. There are said to be more wild camels in Australia than in Arabia and these too can be captured by such a system.

At the start of the 1990s, Fututech was hailed as the future of slaughterhouses [56.76]. Robotic systems to be installed at the Kilcoy pastoral company in Queensland would automate the whole process from the *knocking box* to the chillroom. Construction started in 1992, but by June 1994 the project was abandoned, at a cost of over \$40 million [56.77]. It was a project that was ahead of its time, relying on a central computer and kilometers of cabling rather than distributed intelligence.

But much is different now. Robots have become commonplace in abattoirs, supported by sophisticated sensing systems to locate skeletal features [56.78] (Fig. 56.35). Pigs probably outnumber cattle and the processed animals include sheep and goats. Deboning systems are marketed for products including chicken legs and ham bones [56.79, 80].

For slaughtering quantity, the lead must be held by poultry, where a single plant can process up to 4000 birds per hour [56.81].

Fig. 56.35 Lamb processing

56.3.20 Aerial-Based Precision Agriculture

Unmanned aerial vehicles (UAVs) have recently begun being applied to precision agriculture. This is a new development and results are still preliminary, albeit very promising (📺 VIDEO 307). In fact, the Association for Unmanned Vehicle Systems International forecasts that 80% of all UAVs sold in the United States in the 2015–2025 period will go to serve the agricultural market [56.82]. Even if the actual figure turns out not to be that high, there is no question that roboticists and agricultural engineers are investing significant time and resources to understanding how UAVs can improve agricultural efficiency and reduce costs.

Dong et al. [56.83] use high-resolution images and on-board sensor data from an aerial vehicle (Fig. 56.36) to create a sequence of dense 3-D reconstructions of the crop over time. This four-dimensional (4-D) spatio-temporal reconstruction is used to segment the canopies and estimate how the crown radius and height of each plant evolve. The processing pipeline was tested on data collected in a field planted with corn, broccoli, and cabbage in Tifton, GA, USA (Fig. 56.37).

Fig. 56.36 AscTec Pelican quadrotor used for data collection over early season sweet corn

In many potato growing areas, the potato crop does not senesce naturally and therefore tuber maturation is artificially induced by killing the haulm 10 to 25 days prior to harvest. Reglone is a widely-used potato haulm killing herbicide. Building on the knowledge of the relationship between potato crop biomass status, expressed in weighted difference vegetation index (WDVI) [56.84], and the minimum effective

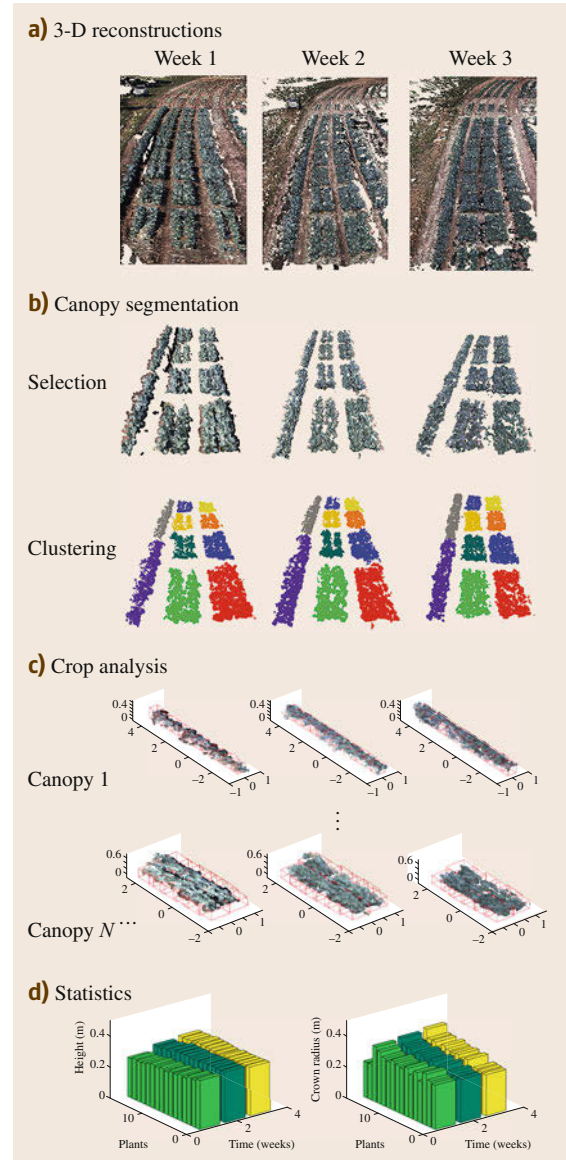

Fig. 56.37a–d Dense 3-D reconstruction of the corn stalks, used to estimate how the crown radius and the height of each plant evolve over time. (a) 3-D reconstruction of crop, (b) canopy segmentation, (c) crop analysis and (d) crop statistics

Fig. 56.38 Operator launching an unmanned aircraft over a potato field via a launch rope. The plane then flies autonomously following a pre-programmed flight path

Fig. 56.39 (a) Weighted difference vegetation index (WDVI) map of a potato field; the legend on the bottom represents the WDVI, which varies from zero (no crop at all) to one (theoretical maximum). A vigorous potato crop has a value in the 0.6–0.7 range. (b) Reglone dose task map; the legend represents dose in liters per hectare

dose of Reglone, *Kempenaar et al.* [56.85] successfully demonstrated the use of crop biomass imaging with a multi-spectral camera underneath an unmanned aircraft (Fig. 56.38) for variable rate application. The

Fig. 56.40 Fixed-wing UAV launched over a black-grass-infested wheat field

WDVI map was converted into a 33 m × 10 m dose grid map (Fig. 56.39) adjusted to the boom width of the field sprayer. On the field, the average use was 0.9 liters of Reglone per ha, with satisfactory efficacy. Standard practice would have been the use of 2 liters per ha. The use of unmanned aerial imaging thus prompted a savings of more than 50%, without loss in potato haulm killing efficacy, harvestability of the potatoes, and final product quality.

Wheat is the most widely grown arable crop in the UK, covering around 1.6 million hectares and producing 11.9 million metric tons in 2013. As with other crops, wheat has its share of weed competitors, one of which is black-grass. This prolific weed is highly competitive and increasingly resistant to chemical control, making it one of the biggest challenges facing UK's agricultural sector.

Researchers from URSULA Agriculture have demonstrated a system that combines multispectral sensing with UAVs to capture imagery at 10 cm resolu-

tion (Fig. 56.40) [56.86]. Using the unique spectral and morphological properties of the black-grass, they developed classification processes that are applied to the image to automatically delineate the black-grass from the host crop.

For the farmer and agronomist, the output is supplied in the form of visual maps and spatially attributed data points that are transferable through farm planning software to precision guided machinery (Fig. 56.41). URSULA Agriculture's imagery analysis is able to not only identify the location and in-field extent of black-grass infestation, but also the density and area of black-grass plants, all of which will have a bearing on control decisions. The information provides the farmer with vital data to help contain black-grass infestation in the current growing season. Crucially, it also helps with long-term control by informing management methods such as higher seed rates to increase competition in black-grass *hotspots*, alternative cultivation techniques, or adjusting cropping strategies, all of

Fig. 56.41a–b Black-grass analysis stack: High-resolution multispectral image (a), black-grass delineation (b), and density map (c)

which can help control black-grass alongside chemical herbicides.

56.4 Conclusion

The robotics community has made great strides toward introducing robotic systems in agriculture and forestry. The next ten years will bring improved sensing and mobility, and some advances in manipulation for crop production.

In orchard crops, there is still a need for improvement in algorithms that calculate crop yield and canopy volume or that automatically detect insects and disease. Here the breakthroughs may end up coming from physicists and engineers producing novel imaging systems rather than from roboticists. The continued conversion of existing orchards to the *tree wall* architecture means that autonomous orchard vehicles and platforms will soon have access to the vast majority of the fruit production acreage, at least in developed countries.

Manipulation in orchard environments is a growing and challenging field. The long-sought *harvesting robot* is still an object of fiction, especially when it comes to its economic feasibility. In the apple industry, for example, the best human workers are capable of picking 40 to 60 pieces of fruit per minute, keeping bruising down to a few percent of the volume picked. Our community is relatively far from achieving this level of performance, but we do not need to get there in one shot. Many value-added operations, including pruning, thinning, and harvesting, could benefit from an automated manipulation-based solution. Manipulation should be introduced into low-precision tasks first, where economic gains can be more readily realized, be-

fore the technology is refined and directed at tasks such as apple picking. One example is automatic grape shoot and fruit thinning according to each individual vine's crop load [56.87]. This is in contrast to today's methods, where crop load management is conducted uniformly over the entire vineyard, leading to significant variations in yield. Achieving vine-level manipulation in an economically sound way would help move the grape industry in the direction of variable rate management, so that one day, each vine, leaf, and fruit will be treated individually according to its own needs of water, nutrients, light, etc. [56.88].

Despite more than thirty years of research, robotic systems for plant maintenance operations in protected cultivation have not become commercially available. Clearly, the complexity of the operation is an issue. This is due to the highly unstructured working environment, the inherent natural variability of the crop, and the unfavorable environmental conditions, e.g., strong variations in lighting. In this domain, robust sensing and perception is key to successful deployments. This includes aspects such as detection of fruits, stems, and leaves, determination of their properties, e.g., ripeness, and, finally, their accurate localization in the 3-D working environment. Object detection can be quite a challenge as in some cases it boils down to finding a green object in a green background. When color differences are more pronounced detection can be easier, but still in many cases object occlusion poses another problem.

This does not only prevent proper detection of the fruits, but also adds difficulty in the proper assessment of their properties.

In the cluttered environments of protected cultivation, manipulation is also quite challenging. While performing a task, the robot should prevent damage to the crop as this will immediately reduce its value. Still, the robot should be allowed to hit objects such as leaves. Humans tend to have quite intensive contact with the crop during operations. To mimic this kind of behavior requires knowledge about whether objects should not be touched at all or whether they might be gently touched and pushed aside, employing a kind of compliant motion.

Generally speaking, robotics-based crop production can be seen as an instantiation of the hand-eye coordination problem, or the integration of effective sensing, perception, and intelligent manipulation; in other words, those aspects of a well-trained human that are hard to reproduce. Development of technology to mimic human behavior is one way to go, but it will always be limited by the environmental conditions found at the time the robot was introduced. A systemic approach where the crop production system is designed top-down with the robotic system as just one of its components is a much more promising route, yet one that is still in its infancy. For example, growing systems can be modified to make detection and the approach of fruits and flowers easier, thus allowing for more simple design and operation of automated systems. Likewise, cultural practices may be modified to include the robot as part of the task [56.89, 90]. Human-robot interaction might be an interesting and cost-effective intermediate step – allowing for human

guidance and supervision only when the machine needs assistance. Such collaborative approaches facilitate data collection in real working environments, offering the opportunity for learning and improving algorithms, thus paving the way for fully autonomous operations in the future.

Another important aspect of the successful introduction of robots in agriculture and forestry is that related to the socio-economic barriers to adoption. In addition to being able to execute a task correctly, the robot must do it in a cost-effective way. Such efficiency can only be demonstrated via numerous field trials, which are time-consuming and costly. Furthermore, the robotic system must have a total ownership cost, including acquisition, maintenance, user training, and disposal, that is less than the financial gains leveraged through its introduction in the production process. Finally, one fundamental aspect is safety. Not only must the hardware and software be designed and validated based on explicit safety requirements, there must be standards and regulations that dictate how and when robots and humans can interact. For an example of a study on the socio-economic barriers to adoption in the apple industry, see [56.91].

The mechanization enabled by the Industrial Revolution and the automation enabled by the information technology era have revolutionized agricultural production to the point where a single farmer can produce grains to feed one hundred people. In the next fifty years, we will witness a similar occurrence in fruits, vegetables, and other crops, thanks to the advances in robotic technologies that our community is continually developing for and applying to agriculture and forestry (👁️ VIDEO 93).

57. Robotics in Construction

Kamel S. Saidi, Thomas Bock, Christos Georgoulas

This chapter introduces various construction automation concepts that have been developed over the past few decades and presents examples of construction robots that are in current use (as of 2006) and/or in various stages of research and development. Section 57.1 presents an overview of the construction industry, which includes descriptions of the industry, the types of construction, and the typical construction project. The industry overview also discusses the concept of automation versus robotics in construction and breaks down the concept of robotics in construction into several levels of autonomy as well as other categories. Section 57.2 discusses some of the offsite applications of robotics in construction (such as for prefabrication), while Sect. 57.3 discusses the use of robots that perform a single task at the construction site. Section 57.4 introduces the concept of an integrated robotized construction site in which multiple robots/machines collaborate to build an entire structure. Section 57.5 discusses unsolved technical problems in construction robotics, which include interoperability, connection systems, tolerances, and power and communications. Finally, Sect. 57.6 discusses future directions in construction robotics and Sect. 57.7 gives some conclusions and suggests resources for further reading.

57.1 Overview	1494
57.1.1 Industry Description	1494
57.1.2 Automation in Construction	1496
57.1.3 Classification of Robotics in Construction	1496
57.2 Offsite Applications of Robotics in Construction	1499
57.2.1 Robotics in Component Production	1499
57.3 Onsite Applications of Single Task Construction Robots	1504
57.3.1 Steel Welding	1504
57.3.2 Reinforcement Manufacturing and Positioning	1504
57.3.3 Concrete Distribution	1504
57.3.4 Robots for Customized Construction On-Site	1505
57.3.5 Robotic Interior Finishing	1506
57.3.6 Robotic Facade Operation	1510
57.3.7 Earthmoving	1511
57.3.8 Road Maintenance	1511
57.3.9 Material Handling	1511
57.4 Integrated Robotized Construction Sites	1511
57.4.1 Robotic Roof Field Factory Approach	1511
57.4.2 Robotic Field Factory on-Ground Approach	1513
57.4.3 Robotic Deconstruction and Robotic Recycling	1513
57.5 Currently Unsolved Technical Problems	1514
57.5.1 Interoperability	1514
57.5.2 Structural Connection Systems	1514
57.5.3 Tolerances	1515
57.5.4 Power and Communications in the Field	1515
57.5.5 Sensing	1516
57.6 Future Directions	1516
57.7 Conclusions and Further Reading	1516

Construction is a ubiquitous human activity that relates to the creation or realization of physical artifacts or custom-made capital goods. It is distinguished from

manufacturing in that the production activity normally occurs in a field setting and is undertaken in the open air, on natural terrain, and often with naturally oc-

curing materials. Typically, building and construction products are large in scale and unique in form. Moreover, the environment or field setting is typically unique and requires a, rather ad hoc, *factory* to be synthesized on site.

Over the centuries, various forms of machines and mechanical engineering systems have been introduced into the construction engineering domain and into the building and construction industry to increase production efficiency. In common with the fields of agriculture, mining, and forestry, the long-term trend has been for these fields to become increasingly mechanized [57.1].

In the last few decades, with the decrease in the relative cost of machinery to labor and with the globaliza-

tion of markets, the construction industry has become significantly more capital intensive and large-scale machinery systems and pieces of construction plant – such as tunnel-boring machines and very large tower cranes – have become commonplace. This trend to mechanization is likely to continue with the progressive introduction of computer-controlled construction machinery and flexible manufacturing concepts into the industry.

With the relatively recent development of the micro-processor and the availability of low-cost computer and sensing technology, construction robots have become a technical and economic possibility and this form of technology is now gradually being used in the industry.

57.1 Overview

The application of robots in construction traditionally falls under *construction automation*. As the term implies, the field of construction automation is focused on automating construction processes, and the use of robots is but one aspect of automation. Construction processes also fall within several categories best described through a brief introduction to the construction industry.

57.1.1 Industry Description

The construction industry typically accounts for 5% of a country’s gross domestic product (GDP) or gross value added (GVA) and employs a significant portion of the country’s workforce. Table 57.1 presents some of these statistics for the USA, the European Union (EU), Japan and China [57.2–8]. Worldwide, construction industry *spending* was estimated at approximately 11% of the world’s GDP at the end of the 20th century [57.9].

Construction is considered by many to be technologically behind other industries, such as manufactur-

ing. In manufacturing, a product is designed for mass production, whereas construction *products* (or projects) are usually one-off and unique [57.10]. Thus the efficiencies achieved through mass production are not easily achieved in construction.

Other often attributed reasons for the construction industry’s technological lag are the industry’s fragmentation and aversion to the risks associated with the introduction of new technologies [57.10, 11]. For example, in the US in 2010 firms with fewer than twenty employees employed approximately 40% of all construction workers, and 63% of all construction workers worked for specialty trade contractors who accounted for 64% of construction firms [57.10]. Specialty trade contractors are usually subcontractors on a project and are not responsible for the overall outcome of the project.

In addition, unlike their manufacturing counterparts, construction sites are for the most part unstructured, cluttered, and congested, making them difficult environments for robots to operate in. Furthermore, human workers are also present in large numbers on a construction project, making safety a paramount concern.

Table 57.1 Value of construction put in place and number of construction workers for the USA, EU, Japan and China

Country	USA	EU	Japan	China
Data period (year)	2012	2009	2011	2011
Value of construction put in place as percentage of national GDP/GVA (%)	5	7	10	7
Number of construction workers as percentage of the total national workforce (%)	5	11	10	5
Total number of workers in the national workforce (million)	112	175	63	784

Types of Construction

Construction projects are usually classified as residential, commercial, industrial, or civil. Residential construction generally involves single-family homes or large apartment buildings; commercial focuses on building structures such as office and retail space, warehouses, and so on; industrial is involved in building factories, power plants, and other similar structures; and civil construction focuses on public infrastructure such as highways, bridges, tunnels, and dams.

The Typical Construction Project

A construction project typically goes through six major phases, as shown in Fig. 57.1. Some projects may go through different variations of the sequence shown, but most projects include planning, design, construction, and operation phases [57.4, 10]. Phase 1 begins when a need for a project arises and the requirements are identified. Phase 2 involves developing alternative project plans that could meet the identified needs and evaluating the technological and economic feasibility of each alternative. Phase 3 develops detailed engineering designs and specifications for the plan selected in phase 2. The construction of the facility from ground-breaking through to final inspection takes place in phase 4 of the project. The facility is occupied and commences operation in phase 5 and continues operating until it is time to shut down and dismantle the facility once it becomes obsolete (phase 6).

The actual physical work (building, operating, maintaining, and dismantling) on a construction project takes place in the last three phases. Although these are the only phases in which machines are used, construction automation can also take place during the other phases of a project, as described in Sect. 57.1.2.

During the various phases of a construction project, several stakeholders may be involved at any time. The major stakeholders include the following: the *owner* and *operator*, whose needs initiated the project; the *architect* and *engineer*, who have the task of translating the owner's needs into an aesthetically pleasing and structurally sound design; and the *general contractor*, whose task is to translate the design into a physical structure. In addition several other stakeholders may be involved either independently from the above stakeholders or as part of their organizations; for example, the constructor may employ a project manager, a construction manager, a site superintendent, and others, and he/she will typically subcontract major activities such as excavation and concrete pouring. The subcontractors and sub-stakeholders are often the ones who use a new technology and can either *make or break* its implementation.

Although the builder is the most likely user of robots on a construction project, the actual work on site is often conducted by subcontractors who often are reluctant or financially unable to use advanced technologies which have not been entirely adopted by industry. A constructor's goal is often to meet the owner's requirements by the most efficient and least risky methods possible. Hence, traditional construction methods that have stood the test of time are preferred. Nevertheless, it has often been anecdotally reported that the owner has *the power* to require the use of certain technologies on a construction project, since that shifts

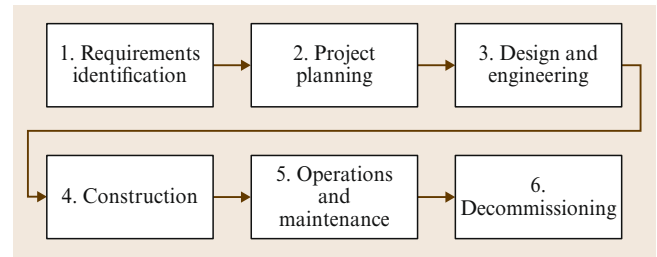

Fig. 57.1 Phases of a typical construction project

part of the risk and cost associated with the use of the technology to the owner. This phenomenon may be partially responsible for the widespread penetration of laser scanning technology into the construction industry that is currently taking place [57.12].

Typical Construction Processes

From a purely physical-world and practical point of view, construction may be viewed as being comprised of a finite number of elementary processes [57.13–16], which may be summarized by the following list [57.11]:

- Attaching
- Building
- Coating
- Concreting
- Connecting
- Covering
- Cutting
- Digging
- Finishing
- Inlaying
- Inspecting
- Jointing
- Measuring
- Placing
- Planning
- Positioning
- Spraying
- Spreading.

Most of these processes can also be grouped into three predominant types of functional operators as follows:

- Materials handling (by bulk and unit load)
- Materials shaping (cutting, breaking, compacting, and machining)
- Structural joining.

These functional operators are typically each applied to multiple operands. Common operands in build-

ing and civil engineering are steel and other metals, concrete, timber, earth and rock, masonry, plastic and glass, cement, aggregate, epoxy resin, bitumen, and other bulk and formed materials.

57.1.2 Automation in Construction

Construction automation describes the field of research and development focused on automating construction processes, and the use of robots is but one aspect of that field. In short, construction automation deals with applying the principles of industrial automation to the construction sector, whether in building construction, civil engineering (roadways, dams, bridges, etc.), or in prefabrication of construction components [57.17]. This can be viewed as an extension to research in field service robots generally designed to replace or assist humans in a specific construction-related task or function.

From a historical perspective, research in construction robotics and automation started in the 1980s with the introduction of single-purpose robots (principally remotely controlled, or teleoperated, machines). The Japanese led this effort, driven primarily out of concern for societal demographics, which showed a significant future shortfall in personnel available for the construction labor pool [57.18]. In the US the principal related work involved developing remote control or teleoperated machinery for hazardous work that required modified construction equipment. Example applications include robots developed for rapid runway repair and unexploded ordinance removal. In the EU, research was focused on the development of large-size masonry (brick laying, assembly) robots for residential and industrial building construction.

During the next decade, as research on task-specific construction robots continued, large Japanese construction firms introduced on-site *factories* for high-rise construction. These construction systems included just-in-time delivery of components, automated part tracking and material handling, robotic connection and assembly, and centralized control in an enclosed or semi-enclosed environment. It is reported that the systems enable better working conditions (weather invariant) and reduced project completion time [57.19]. Other benefits include improved productivity and quality, though overall construction costs are not necessarily lower [57.20].

Advanced concepts in integrated residential construction automation were developed as part of the EU FutureHome project. In this construction concept, each structure consists of several high-quality, prefabricated three-dimensional (3-D) modules and two-dimensional (2-D) panels which are assembled *production-style* on site [57.21]. An analogue of this approach for auto-

mated residential construction has been commercialized in Japan [57.22].

New methods for collecting, processing, analyzing, and communicating construction information are a significant area of construction automation research [57.23]. This research includes data interoperability and exchange through the design, construction, operations, maintenance, and decommission phases of a capital project [57.24]; advanced sensors for assessing the status of the construction process [57.25–27]; visualization systems for planning construction events, verifying constructability, and maintaining site situational awareness [57.28–30]; and information models which extend traditional computer-aided design (CAD) modeling to combine both the physical (geometric) and functional characteristics of building components [57.31].

Finally, three notable, large-scale, EU projects attempted to integrate construction automation into the way construction projects are executed: the ManuBuild (open building manufacturing) project dealt with, among other things, the development of mobile field factories, including robots, for on-site modular construction [57.32]; the I3CON (industrialized, integrated, intelligent, construction) project dealt with the indoor automation and robotization of buildings [57.33]; and the Tunconstruct project dealt with the robotization of inspection and maintenance operations in tunnels [57.34].

57.1.3 Classification of Robotics in Construction

Construction robotics is an advanced form of mechanization (automation) in which an endeavour is made to automate some industrially important operation and thereby reduce the cost of this operation by either removing a human operator *from the control loop*, or enhance operational efficiency through machine control systems. Due to the nature of construction work, most robots which have been developed for the construction industry are either mobile or relocatable systems. Some platforms, such as floor-finishing robots and machine-controlled earthmovers require mobility as a specific function of the work process to be performed. Others, such as wall and ceiling panel manipulators, require some level of mobility to extend their operating workspace.

Robot terminology can vary depending upon the research discipline. For this chapter two broad classifications of construction robotics are onsite robots and offsite robots. These are distinguished by whether they are applied at the construction site or at a factory or prefabrication facility. In addition, a further distinction can

be made depending on whether a construction robot is intended to be used for a single task (onsite or offsite) or whether multiple robots are integrated into an automated construction site.

Single Task Construction Robots Versus Integrated Robotized Construction Sites

After the initial experiments in large-scale industrialized, automated and robotized pre-fabrication of system houses were conducted successfully in Japan, and the first products (e.g. Sekisui M1) also proved successful in the market, in 1975 a Japanese construction contractor, Shimizu Corporation in Tokyo, set up a research group for construction robots. The goal was now no longer the mere shifting of complexity into a structured environment as in prefabrication, but the development and deployment of systems that could be used on the construction site to create structures and buildings. The focus initially was set on simple systems in the form of so-called single task construction robots that can execute a single, specific construction task in a repetitive manner.

Single-task construction robots are systems that support workers in executing one specific construction process or task (e.g. digging, concrete levelling, concrete finishing, painting) or completely supplement the physical activity of the human workers necessary to perform this one process or task. Further, the processes and tasks they support or supplement can be allocated to a specific profession or craft. In addition, the processes and tasks for which single task robots were developed had in common that they entailed frequent, repetitive activities. Common characteristics of single-task construction robots are as follows:

- Highly specialized not only for a profession but even for a task within a profession (e.g., concrete pouring, levelling and finishing).
- Enhanced productivity compared to conventional labour. E.g., according to [57.17] the conventional labour productivity rate for concrete floor finishing is between 100 m³/h and 120 m³/h, whereas the productivity using machines is between 300 m³/h and 800 m³/h.
- Improved quality through precise control of functions and operations (e.g., uniform distribution of paint) and by allowing real time monitoring (and recording) of the operation.
- Improved working conditions by removing workers from dangerous environments and reducing the amount of and heavy physical work.
- Most robots allow various operation modes such as autonomous or sensor guided, pre-programmed, or tele-operated.
- Reduced material consumption through precise control of material delivery and collection and reuse of unused material.
- Most robots have simple yet robust sensor technologies, such as gyroscopes, simple laser systems, or touch/pressure sensors.
- Most robots only require 1 or 2 persons to operate.

The evolution of industrialized and automated building prefabrication during the 1970s along with the development of single tasks robots, envisioned the concept of integrated robotized construction sites. This concept combined prefabrication technology (processing of prefabricated components instead of parts in order to reduce complexity on the site), single task construction robotic systems, and moving or stationary site factories that were able to assemble the building's main structure (e.g., steel frame or concrete structure) almost automatically. As those site factories not only automated parts of the construction process but also integrated prefabricated component technology and single task automation can thus be called as integrated robotized construction sites.

A major reason for the transition into integrated robotized construction sites was that the construction companies realized that single task construction robots which were not networked or embedded within a greater infrastructure, turned out to be incompatible with the way buildings were designed and built. Single task robots were designed to execute certain tasks meanwhile construction workers were not allowed to interfere significantly with the robots activity. However, it turned out that under these premises, only a very few number of robots could be used efficiently. The constraints for the workers, the necessary safety regulations, coupled with the unforeseen, unpredictable, and dynamic processes at the construction site, led to the implementation of individual robots working in parallel. Although single task construction robots achieved a high throughput, significant time had to be spent on-site for transportation, preparation, programming, configuration, etc. Besides the mentioned frictions single task construction robots caused on (conventional) construction sites, the emergence of concepts for integrated sites was also nurtured by the new technological possibilities. Important for the integration of such systems into larger and coordinated automated systems was the development of systems that allowed controlling and monitoring an uninterrupted flow of information and material on-site, between individual automated entities that are involved in the final assembly of the building.

The transition to integrated sites can also be explained from an evolutionary view. In many industries

the evolution from more workshop like production with individual and only loosely coupled production entities or stations, to flow-line like or production line like systems with stable processes and continuous material flow was part of the evolution of other well established and known industries,, i.e., automotive, computer industry.

Finally, three general categories of construction robots are introduced. The first class is *teleoperated systems*, which for simplicity includes *remote control systems*. The general distinction between the two terms is whether or not the equipment must be operated in line of sight from the human controller [57.35]. The second category, *programmable construction machines (PCM)*, includes most construction equipment that is outfitted with sensors and mechanisms to augment operation by an onboard human operator. The final category, *intelligent systems*, relates to unmanned construction robots which operate either in a semi- or fully autonomous mode. In Sect. 57.3 this classification will be expanded to include examples based on various generic activities, materials handled (operand types), levels of onboard intelligence, levels of commercialization, and levels of system integration and computer integration.

Teleoperated Systems in Construction

In established engineering terminology, the term *teleoperation* refers to the remote control of machines and systems. In teleoperation (loosely referred to as telerobotics) the control of the machine is accomplished by the use of remote control means such an umbilical cord or wireless control. Teleoperation ideas and methods are used extensively in the space and nuclear industries (Chaps. 55 and 58, respectively).

In telerobotics, the machine does not operate autonomously but is under the control of a human. Data sensing and interpretation and cognitive activities such as task planning are done by the operator.

Recently, many telerobotic devices have appeared in the construction and mining industries. These machines have evolved in response to industrial situations where there is danger to the operator and where remote-controlled machinery is necessary (e.g., teleoperated small compactors). Situations of this kind occur in the construction, demolition, and mining industries and in other hazardous locations.

The technology for telerobotics in construction is well established, with a number of excellent examples of such activity available, for example, a sophisticated model-based supervisory-control-type distributed teleoperation system for the construction of a trench for

a diversion dam in a lava field in Japan using a fleet of heavy earthmoving machines [57.36].

Programmable Construction Machines

A software-programmable construction machine is what most people would consider to be a robot. The operator of this type of machine is able to vary the task to be accomplished within certain constraints either by choosing from a preprogrammed menu of functions or by *teaching* the machine a new function. Variations in the task to be accomplished could be as simple as slight changes in the driving speed based on the current load for an automated forklift, or as complex as a change from being able to pick and place steel beams and columns using an autonomous crane to being able to deliver concrete autonomously using the same crane.

Generally, software-programmable construction machines are identical to traditional construction machines (such as an excavator), but have been modified to be controllable through a computer (similar to the way in which traditional manufacturing machines – such as mills and lathes – evolved into computer numerically controlled (CNC) machines).

Software-programmable construction machines can make use of an electronic representation of a portion of the construction site where their work is to be conducted in order to control all or part of the machine's operation. A commercialized example is *stakeless grading*, where data from a 3-D model is used in combination with global positioning systems (GPS) and/or laser measurement systems to automate the blade control for bulldozers and motor-graders.

Intelligent Systems in Construction

As opposed to a teleoperated or a software-programmable construction machine a fully autonomous construction robot is expected to accomplish its task, within a defined scope, without human intervention. A semiautonomous construction robot would be expected to accomplish its task with some level of planning interaction conducted with a human supervisor [57.35]. In each case the construction robot is expected to adapt to its sensed environment, formulate plans for the execution of its task, and replan as necessary (with possibly some human assistance in the semiautonomous mode). The intelligent construction robot should also be able to determine when its tasking is not executable and request assistance.

Example research in intelligent construction systems includes autonomous excavation [57.37, 38] and autonomous crane operations [57.30, 39–41].

57.2 Offsite Applications of Robotics in Construction

The infusion of technologies (such as computer aided design (CAD), computer aided manufacturing (CAM)) into the construction industry from other industries (such as the automotive, airplane and shipbuilding industries) are the clearest proof for a shift in building strategy. Fully automated concrete fabrication is currently a reality that are implemented by factories with customized product delivery in order to adapt to the changing requirements of the market. There are two major industrialized production methods for prefabricated concrete: Production methods that (a) use stationary single formwork and (b) that use mobile formwork.

57.2.1 Robotics in Component Production

Production methods using stationary single formwork comprise mobile workflows such as cleaning, pouring/casting and moving the final product to the storage, while the formwork is stationary during the whole process of prefabrication. In production methods using mobile formwork, the work posts are stationary while the formwork is mobile, moving into the various prefabrication posts of the assembly line.

Concrete Production

A plant for combined manufacture of 2-D and 3-D precast concrete elements includes overhead gantry cranes and electric hoists, used to transport consumable materials (such as lattice girders, steel coils, and parts to be

inserted/installed) as well as to lift elements from the concreting station into the storage facility or onto transport pallets. Pallets start at the discharging station, from where they proceed via the pallet cleaning station to the first workstation. There, by means of a de-palletizing device attached to a panel-stacking crane, the finished flooring elements are lifted off the pallets and stacked directly within the working range of the discharging vehicle. A cleaning and plotting (magazining, cleaning, plotting (MCP)) robot is used for a variety of tasks: picking up, insertion of latitudinal anchors, cleaning of pallets, full scale plotting of elements, and installation of latitudinal anchors (Fig. 57.2). Figure 57.3 shows further examples of robotic concrete component manufacturing and handling.

Brickwork Component Production

Since the late 1970s, due to the lack of skilled workers in construction and increasing costs of buildings, rationalization developments were started. They mainly took place in the masonry and the formwork sector, where no ready solutions from other countries were available. In Germany and also in most parts of Europe an often used and still loved building material is brickwork. Most of the building projects are constructed with this material. Due to the lack of brickwork in Japan (not resistant to earthquakes if not reinforced), and missing developments in other countries, main efforts were made in this field.

Fig. 57.2 (a) Pallet in concreting station; (b) bridge crane; (c) pallets molding systems; (d) demolding-depalletizing device; (e) cleaning, measuring and oiling (after [57.42])

Fig. 57.3 (a) Automated concrete pipe manufacturing machines (courtesy Hawkeye Group USA); (b) precast concrete handling robot (courtesy Halo, Inc.)

In the last few decades activities to develop machines that support the laying of bricks and even automated robots have been increasing, especially in Germany. Brick laying is a very labor-intensive activity, which can lead to significant health issues and early retirement [57.43, 44]. Consequently a very small number of skilled workers is available nowadays. This in turn is reflected in ultimately high prices and wages, which will make brick building in some time prohibitively expensive. Therefore it should just be a question of time before only houses are put on the market that have not been erected on site by a team of bricklayers, but by a robot in the production shop.

Early Trials of Robotic Assembly of Modular Blocks

One idea for Robot Oriented Design (ROD) [57.45–47], in building construction is to change the conventional construction works adaptable to robotics so that construction system and advanced automation and/or robotics are co-adapted. Thus a structural system for the wall erection named SMAS (Solid Material Assembly System) [57.48] was proposed and developed already in the 80s in Japan. SMAS is a of reinforced masonry construction system. A standard building component of this system, 30 cm × 30 cm × 18 cm in size and 20 kg in weight, is made of pre-cast concrete and includes cross-shaped steel bar inside each component for the reinforced of structural wall. Components are positioned automatically by the robot one by one without arrangements of conventional bonding. Following the positioning of each components, steel bars are connected to those of adjacent components also by the robot. The joint type of steel bar for vertical direction is mechanical, and that for lateral direction is overlapping. Concrete is grouted from the top of the wall which is erected one storey high (about 3 m). The newly developed operating hand is installed to the mother robot (6-articulation-type robot) which was developed

for a wide variety of applications in factory use and a series of experiments for wall erection were carried out.

The rapid progress being achieved today in the modernization and industrialization of building construction technology has triggered a trend to reduce the complicate works at construction site and increasingly produce building components at factories. It is obviously that the prefabrication has been successful in up-grading the quality of the building and in shortening the construction period. The sizes of those building components such as prefabricated structural members are also becoming larger to simplify assembling work at the construction site.

However, these movements are not necessarily oriented toward the introduction of robots. The heavy and large components are difficult to be operated by the robots and the complicated assemble techniques are sometimes too skilful for robots. Meanwhile, when one looks at the prefabrication of compact and lightweight structural components as a means of accomplishing construction work more efficiently, robots can be used for assembling these structural members efficiently.

From this point of view SMAS structural system was developed and proposed as a robot-oriented construction system. A masonry structure has not been considered as a major structural system in Japan because of earthquakes; however, it becomes to be recognized as a flexible structural system applied to various building designs when properly reinforced. In addition, it has advantages in the construction cost and in the construction period. The SMAS system itself was designed as a modular system for the purpose that single components could be developed further in the future. All system components including stones are developed as complementary parts according to the guidelines of Robot Oriented Design (ROD) (Fig. 57.4). These robotic approaches were meant to be applied on-site, but technologically they were proven to be not effective. Thus, they became better suited for offsite assembly operations.

Fig. 57.4 (a) Building component developed by guidelines of Robot Oriented Design (ROD), (b) SMAS total system, (c) robot end-effector/gripper with optical fiber sensor guiding screwing mechanism

Automated Brickwork Plants

The adoption of CAD/CAM systems combined with implementation of Enterprise Resource Planning (ERP) Solutions has made the implementation of advanced technically refined, fully automatic production plants possible:

- High degree of information and communications technology (ICT) integrated and automated/inter-connected processes
- Integration of as many devices as possible by ICT (interoperability)
- CAD/CAM Systems
- Integration of processes by ERP Systems
- Just in Time and Just in Sequence supporting customization.

Brickwork Robot Plant SüBA

Crucial technical developments preceded the construction of a fully automatic brickwork machine. The prototype of the automatic brickwork plant was developed by the company SüBA in Hockenheim, and the company Windhoff AG in Rheine at the beginning of the 1990s. The production of brickwork panes is appropriate for a capacity of 300 m² net area of brickwork panes – without windows and door recesses – in a shift of eight hours. The employment of CAD in the archi-

tect's offices made it possible to transfer the large data set for the production of brickwork panes directly without manual input over CAM to the brickwork robots. Considering the large number of data for the automat, which was necessary for the production of a brickwork pane, this was one of the most important problems of the automation of bricking at that time. Figures 57.5 and 57.6 give an overview over the most important SüBA factory modules and automation processes.

Brickwork Robot Plant Winkelmann (Horizontal Brickwork Panel Production)

Today's fully automated and highly robotized brickwork plants can be distinguished into two basic types: horizontal and vertical brickwork panel production. The brickwork robot plant Winkelmann is a characteristic example for horizontal panel production. All single devices are equipped with Microsystems, interconnected and part of a systemic logistic network. CAD/CAM guarantees efficient data processing between planning section and production. After the delivery standard palettes bricks are brought into processing order by an automated palletizing system with a robot for distribution of bricks (Fig. 57.7a). After that the bricks are taken up by automated de-palletizing system (Fig. 57.7b), which supplies horizontal brickwork layering robot station (Fig. 57.8a). Insertion of reinforcement and house

Fig. 57.5 (a) Automated reinforcement (horizontal) station; (b) mortar dispensing

Fig. 57.6 (a) Brickwork positioning; (b) brickwork alignment; (c) automated reinforcement (vertical) station

infrastructure as well as plastering are done stationary in the factory (Fig. 57.8b) until a finalized and dried-out brickwork panel is delivered to the construction site.

Brickwork Robot Plant Leonhard Weiss (Vertical Brickwork Panel Production)

The brickwork robot plant Leonhard Weiss is a characteristic example for vertical brickwork panel production. Many processes as for example the palletizing and de-palletizing to bring the bricks into factory order are

similar to the horizontal type. Yet the central process of positioning the bricks in given order is done vertically layer by layer. High accuracy robots combined with linear axis are here in charge for the exact positioning. The automated vertical brickwork layering has some advantages in terms of efficient use of the factory area and moreover the firmness of the wall could be improved whereas the exact positioning of reinforcement, cables and other elements of the house infrastructure is done easier with the horizontal type. CAD/CAM combined

with variable production and ICT integrated production allows individually fabricated brickwork panels and necessary variations. Figure 57.9 shows the various steps of the automated vertical brickwork panel construction process.

Steel Component Production

Sekisui Heim introduced an automated steel frame production. One of the basic features is the automated assembling and welding station. Ceiling elements, flooring elements and columns are fed into this station, followed by automatic welding into a frame, which is

used as chassis and bearing structure during the further completion process on the production line (Fig. 57.10). After the automated welding process, the steel frame chassis is streaming through the factory from work step to work step, until all installations have been completed (Fig. 57.11a). The factories of Sekisui and Toyota have gates on both sides of the assembly lines in order to receive material, parts, components and prefabricated bath or kitchen modules, required for the customized production of individual units. All of them arrive just-in-time and just-in-sequence by cooperating suppliers (Fig. 57.11b).

57.3 Onsite Applications of Single Task Construction Robots

The construction of larger buildings that use steel as the structural support system can involve a high total amount of welds. If the design of the columns and beams can be adjusted in order to reduce the amount and variety of welds, welding becomes a highly repetitive operation suitable for being automated.

57.3.1 Steel Welding

Automated welding is able to control and guarantee the quality of the connection between the welded parts to a level similar to (and sometimes better than) that achieved by professional human welders. Manual welding of these and other types of connections requires highly specialized skills that are currently in short supply. Furthermore, conventional welding can have damaging long-term effects on a worker's vision. Simultaneous automated welding on a beam (e.g., from two or three coordinated positions) is even able to ensure that the steel component is not distorted by the welding operation itself and thus improves the quality of the constructed structures. In Fig. 57.12a the Shimizu steel-welding robot is depicted. The robot can automatically weld a column including the corner portions. The configuration of a joint is detected by a laser sensor, and the welding is performed in an optimized way referring to a database. In Fig. 57.12b, the Obayashi Corporation Steel welding robot operates in a similar principle, us-

ing a circular clamp-on type fastener to the column. The welding process is computer-controlled, though workers are still involved in overseeing operations at least for the time being.

57.3.2 Reinforcement Manufacturing and Positioning

Concrete reinforcement operations involve cutting and bending of rebar (reinforcement bars), precise (relative to each other) arrangement of those rebar, binding of rebar and final positioning of the rebar elements or mesh on a floor or in a mold or formwork system. These tasks are labor intensive and hard on a worker's body (e.g., back accidents and damage to a worker's musculoskeletal system occur about ten times more during reinforcement work than during painting work [57.49]). Automated systems mitigate the risks and impacts on the health of workers and enhance the quality of the reinforced concrete structures. Figure 57.13a shows a reinforcement production robot and Fig. 57.13b shows a teleoperated rebar placing robot.

57.3.3 Concrete Distribution

Concrete distribution systems are used to distribute mixed concrete with uniform quality over large surfaces or over formwork systems. Concrete distribution

Fig. 57.15 Concrete slipform road paving machine (courtesy GOMACO Corp.) ◀

or fully automatic. Depending on the surface where the concrete needs to be distributed, concrete distribution systems can be truck mounted, stationary or mobile. In Fig. 57.14a, a track mounted automatic concrete distributor robot (*DB Robo*) can be seen. In Fig. 57.14b a mobile concrete distributor system can be seen, which due to its wheel-based platform, enables an enhanced operating range. Figures 57.15 and 57.16 show other examples of automated concrete distribution systems.

covers the continuous supply with concrete (pumps, hoses), a system which slides in a certain pattern over the area where the concrete has to be distributed and a concrete ejection system. Systems can be operated manually, tele-operated and sometimes sensor-guided

57.3.4 Robots for Customized Construction On-Site

Several masonry-wall erecting robots have been developed to-date. Examples of these are the *SMAS* in Japan

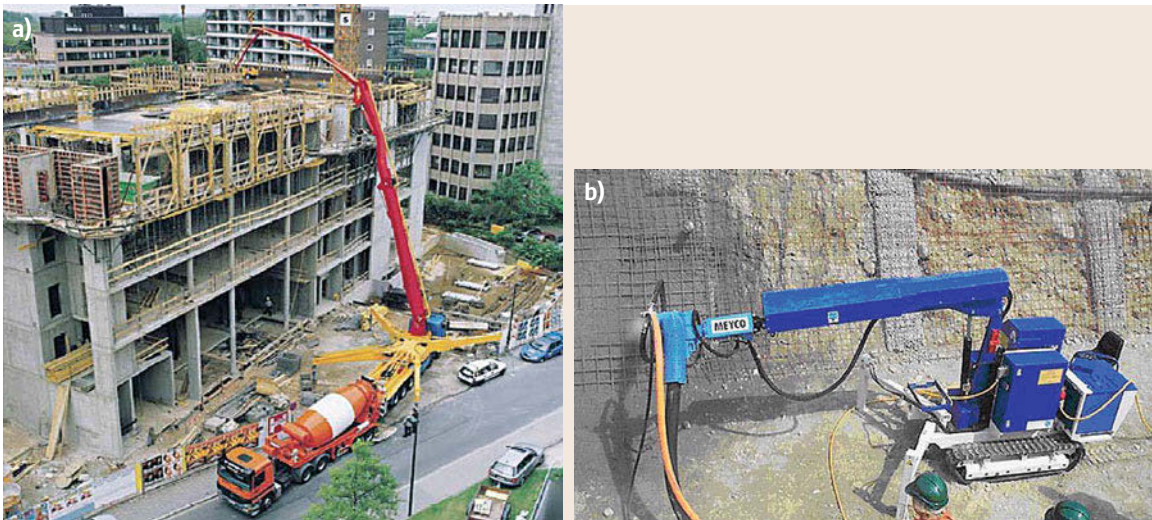

Fig. 57.16 (a) Programmable, articulated-boom machine for the pumped delivery of fresh concrete (after [57.50]) and (b) teleoperated concrete spraying robot (courtesy MEYCO Equipment)

and the **ROCCO** robot at the University of Stuttgart. Many of these systems are still in the prototype stage. The basic concepts that these systems have in common are as follows:

- Autonomous mobility on the construction site
- Sensor systems determine the robot's position and orientation in its environment
- Automatic pick up of the bricks from the pallets
- Automatic application of mortar
- Automatic positioning of the bricks.

ROCCO is a Robot Construction System [57.51, 52], for Computer Integrated Construction (**CIC**). Several companies and institutes participated in this **EU** funded project in an inter-disciplinary and international approach with experts in the fields of construction technology, mechanical and electrical engineering and information technology from Germany, Spain and Belgium. The goal of the project was the development of a computer integrated robot system, which also contains a continuous solution in the **ICT** (Information Communication Technology) for all steps from the architectural design to the automated assembly of the components on the construction site.

The main emphasis of the project lies on the realization of a mobile robot system for construction site operation as well as on the integration of a computer based system for work preparation and quality control. In the work preparation phase the necessary data is generated for the pre-fabrication and customization of the masonry blocks, for the construction site layout and for the automatic robot program generation.

Based on the **CAD**-representation of the building, first the walls are divided automatically into the necessary blocks. In the next step the optimal working

positions of the mobile robot as well as the positions of the pallets and the arrangement of the blocks on the pallets are automatically calculated. With this information the necessary non-standard and standard blocks can be produced and palletized. Finally the robot programs are generated automatically out of the calculated geometry information. The user interface on the construction site is graphically interactive and enables the user to partially re-program the generated robot programs to deal with the uncertainties of the construction process without the need to learn a specific robot programming language.

To test different approaches based on the construction application (residential buildings vs. industrial) and the sensor integration (autonomous vehicle vs. long reach), two systems were developed within the project. The first one, for residential buildings, has a reach of 4.5 m and it is able to handle up to 400 kg. This robot is placed over an autonomous vehicle that allows the movement on the construction site, Fig. 57.17a. Its main task is the erection of walls in residential buildings. The second one is able to handle up to 1000 kg with a reach of 8.5 m. This robot, Fig. 57.17b, is placed over a towable platform and its main task is the erection of external walls in industrial buildings with typical height of up to 8 m and standardized layout.

57.3.5 Robotic Interior Finishing

Interior finishing work is work conducted inside a structure (e.g., an office building) to complete construction of the space within the structure (e.g., painting and false ceiling and gypsum board installation). Due to the confined nature of interior finishing work traditional material handling equipment (such as cranes) cannot be used. The following four systems are examples of interior finishing robots:

Fig. 57.17 (a) Robot for residential buildings; (b) robot for industrial use with long reach manipulator

- The Shimizu CFR 1 (Fig. 57.18a) could be manually and tele-operated and allowed the installation of suspended ceiling panels to a height of up to 3.5 m. The robot's compliant gripper mechanism was able to finely adjust the positions of the panels.
- The Tokyu ceiling panel installation robot (Fig. 57.18b) could position and adjust the panels and also fire nails into the panels to fasten them to the underlying ceiling system.
- Two variants (Fig. 57.18c,d) of interior finishing modular mobile robot, developed in Technical University of Munich.
- The Komatsu Mighty Hand LH (Fig. 57.18e) could position and adjust interior wall panels, glass panels, door frames, window casings and the outside walls (up to 350 kg) with high accuracy.

Concrete Finishing

Floor finishing is one of the most critical construction processes in which construction workers carry or guide trowels over an unfinished, wet concrete floor for several hours in a stooped posture. In order to reduce these physical demands on the workers and to ensure a more uniform finish quality, various companies developed and employed concepts for robots that can perform the concrete-leveling task: the Flat-Kun by Shimizu ($800\text{ m}^2/\text{h}$), the Kote King by Kajima ($500\text{ m}^2/\text{h}$), the Surfing Robo by Takenaka ($300\text{ m}^2/\text{h}$), the Obayashi made by Mitsubishi ($500\text{ m}^2/\text{h}$) and the Floor Traveling Robot MHE by Hazama ($300\text{ m}^2/\text{h}$). Each of these single task construction robots was able to operate on a floor where it was set up into any desired direction (e.g., not only move backwards and forwards and turning but also able to rotate 360° in place).

The finishing mechanism consisted, in most cases, of automatically controlled and operated rotating trowels. The degree of autonomy ranged from systems with human-machine interfaces for tele-operation to systems that could generate motions themselves and to pre-

programming of paths for the robot to follow. In many cases gyroscopes and rotating laser levels assisted navigation and motion planning at a low level. After an intensive research and development phase that lasted until 1985, the first concrete finishing robots were deployed commercially to finish concrete floors in office buildings, factories, warehouses and shopping centers. The use of the robot systems became efficient once a floor plan allowed for a working area that could be processed without interruption of more than 500 to 600 m^2 . Examples of commercial systems are depicted below in Fig. 57.19.

Tile Placement

The exterior of many buildings are sometimes finished with weather-resistant tiles. In Japan single-family buildings, factories, offices and high-rise buildings are often finished with tiles. Tiles are relatively small building elements compared to the total surface area of a building and thus a very large number of tiles have to be installed using the same, repetitive process, which involves applying mortar and positioning the tiles on

Fig. 57.19 (a) Hazama robot; (b) Kajima Kote King robot; (c) Takenaka Surf Robo; (d) auto-leveling concrete screed machine (courtesy Somero Enterprises, Inc.)

Fig. 57.20a,b Hazama tile setting robot; (a) robot upon operation; (b) finished tile setting

top of the mortar. This and the fact that building facades are generally difficult to access make the use of automated systems feasible. Hazama’s tile-setting robot (Fig. 57.20) also showed that accuracy could be enhanced and that the laying of patterns could be ac-

Fig. 57.21a,b Shimizu fireproof coating robots

complished without dramatically increasing construction time.

Fireproof Coating

In many countries building regulations require that steel structures be coated with fire proof materials and/or a fire-retarding paint. The application of the

Fig. 57.23a–c Facade painting robots. (a) Shimizu; (b) Kajima; (c) Taisei

Fig. 57.24a–c Kajima facade inspection robot (a,b); Comatec Robosoft glass cleaning robot (c)

fire-roof coating and paint can only be done after the steel structure has been erected and joined on site (e.g., by welding) in order not to interfere with the joining process and in order to avoid any damage to the fire-proof coating. Therefore, it is not possible to shift the coating operations to upstream production steps that can be performed

in structured factory environments where high efficiency can be achieved. Due to seismic considerations, most high-rise construction involves the use of steel structures and thus, the development and employment of automated and robotic systems that are able to apply the fire-proof coatings after the structure is erected took place in Japan. Robots devel-

oped by Shimizu (Fig. 57.21) and others were mostly autonomous.

57.3.6 Robotic Facade Operation

Facade operations involve the installation of windows, complete facade elements or building exterior walls. Facade elements are, in modern architecture and especially in high-rise construction, decoupled from the main load-bearing concrete or steel structure and can thus be considered as a type of *add-ons*. Facade installation operations are complex operations that involve the accurate positioning of heavy parts or elements at locations that are difficult to access (e.g., high elevations without scaffolding). This involves risk of injury (and thus extensive safety measures must be taken) and of damaging the building or the elements themselves. Furthermore, the positioning and alignment of prefabricated facade elements requires precision and low tolerances. A widespread trend (since the 1980s) of designing large buildings as monolithic structures that repeat the same or similar facade elements, has been a major motivation for investment in automated or robotic systems. Figure 57.22 shows an example of a tele-operated façade installation robot.

Painting

Facade-painting robots were developed to simplify the painting or re-painting of high-rise buildings during construction and operation. Facade painting robots have a particular advantage in that they can keep the paint finish quality constant. They usually have multiple spray nozzles and the spray area is either encapsulated or hermetically sealed in order to avoid streaking. A further advantage of facade painting robots is the fact that workers are not exposed to harmful paint fumes and vapours. Single task, facade-painting robots use one of the following three different strategies to move along the facade:

- Cable-suspended cage/gondola systems
- Rail guided systems
- Vacuum or other adhesion technology.

The use of façade-painting robots was not considered efficient for facades with an area $< 2000 \text{ m}^2$. Facade-painting robots were thus used primarily to paint large facades of warehouses and skyscrapers. Facades to be processed were required to have a low curvature and wherever possible no corners or lugs which can hinder the operation of the robot. Further, the design of window frames as well as the number of windows and the area they cover impact the feasibility and efficiency of facade-painting robots. Between 1984 and 1988 various companies introduced

facade-painting robots. Shimizu and Kajima Corporations of Japan both applied the principle of the suspended cage or gondola (Fig. 57.23a,b, respectively). The Taisei Corporation of Japan used a rail-guided system and combined it with the gondola approach for their robot (Fig. 57.23c). The fastest of the systems (Kajima's robot) worked with a speed of $290 \text{ m}^2/\text{h}$ during the application of the primer paint, $200 \text{ m}^2/\text{h}$ for the base coat and $290 \text{ m}^2/\text{h}$ for the top coat.

Robotized Inspection and Maintenance

Facades of high-rise buildings are in many cases equipped with tiles or other surface panels that have to be inspected regularly during the building's life-cycle in order to detect structural damage and in order to replace tiles or panels that might fall from the facade. Typically, workers access those tiles or panels via cages or gondolas suspended from the roof of the buildings. This work process was considered by Japanese construction firms as monotonous, inefficient and dangerous. Further, since the method for identifying damaged tiles or panels involves listening to the sound a tile or panel makes when gently impacted by a handheld tool, the sounds were difficult to classify at high elevations due to wind noise. Therefore, with substantial financial commitment, autonomous facade-inspection and maintenance robots were developed. Between 1985 and 1988, six different facade-inspection robots were developed in Japan by the Kajima, Takenaka, Obayashi, Taisei, Tamagawa and Seki Corporations. For the inspection of the facade of a 40 m high building (3000 m² facade) an inspection robot needed in average 8 h including ≈ 1 h for task as preparation, configuration, conversions, dismantling and cleaning of the robot (Fig. 57.24a,b).

Today robotic systems are not only developed for the construction of buildings but also for the operation, maintenance and decommissioning of buildings and other construction products. These types of *service* robots were developed for the construction sector for inspection of nuclear power plants, exterior walls of

high-rise buildings and cleaning of high-rise facades or glass roofs (Fig. 57.24c).

57.3.7 Earthmoving

Earthmoving is a construction process for preparing project sites for construction by digging, grading, trenching, scraping and other similar tasks. There have been significant developments in many earthmoving areas and certain tasks (such as grading) can now be completely automated. Figure 57.25 shows several examples of automated earthmoving equipment some of which were still in the research and development phase while other are already commercial products.

57.3.8 Road Maintenance

Figure 57.26 shows three examples of machines that perform pothole repairs and crack sealing on road with various degrees of automation. Figure 57.26a is a commercial product while the other two machines were research projects undertaken by departments of transportation in the US.

57.3.9 Material Handling

The transport and handling of materials is a critical activity at most construction sites. Figure 57.27 shows examples of material handling robots developed under different research efforts.

57.4 Integrated Robotized Construction Sites

The first prototypes for mainly automated high-rise construction sites were put into operation in 1990 and 1991 by Shimizu (Fig. 57.28) after five years in development and a financial outlay of almost sixteen million Euros. Since then, twenty automated high-rise sites have been implemented by different companies (Taisei, Takenaka, Kajima, Maeda, and Kumagai) [57.60, 61].

57.4.1 Robotic Roof Field Factory Approach

An integrated robotized construction site involves the use of semi- and fully-automated storage, transport and assembly equipment and/or robots that are used to erect a building almost completely automatically. It is an attempt to improve the sequencing of construction

Fig. 57.28 (a) Robotic trolleys for transporting and positioning of beams, columns, floor panels, building services units and facades, in Shimizu SMART system; (b) SMART roof field factory view

Fig. 57.29a–c Obayashi ABCS (a) early construction phase; (b) intermediate construction phase; (c) final construction phase

processes and construction site management by using real-time control. This includes an unbroken flow of information from the planning and design phase through programming the on-site robots and controlling and monitoring the construction operations.

The robotic roof field factory approach is typically implemented once the building foundations have been laid. The production equipment, on which the steel con-

struction has been installed with assembly and transport robots, is then covered completely with a roof made of plastic film. Depending on the roof system used, this process takes from three to six weeks after which the robots go into production. Due to the lack of space around building sites in Japan, steel and concrete plants are also often installed to supply parts in 10 min cycles on a just-in-time basis.

Prefabricated parts are checked and then placed in specific depots at the foot of the building or in the building itself where they are readily accessible by the robots. This is where the automated construction process actually starts. As many as 22 robots equipped with automatic crane winches deliver the columns, supports, floors, ceilings, walls and other elements to the floor of the steel skeleton under construction. These components are then positioned and fixed into place almost completely automatically. The steel columns and supports are joined together by welding robots after they have been positioned. The position and quality of the welding seams are monitored with lasers.

In the Obayashi ACBS (Automatic Construction Building System) (Fig. 57.29 and in [VIDEO 272](#)), once a storey has been finished, the whole support structure, which rests on four columns, is pushed upwards by hydraulic presses to the next storey over a 1.5 h period. Fully extended, the support structure is 25 m high; retracted it measures 4.5 m. Once everything has been

Fig. 57.30a,b The AMURAD Construction Strategy: floor-wise up-pushing of the whole building. Kajima, Japan (a) early construction phase; (b) later construction phase

moved up, work starts on the next storey. By constructing the topmost storey of the high-rise building as the roof at the beginning of the building process, the site is closed off in all directions, considerably reducing the effect of the weather and any damage it might cause.

57.4.2 Robotic Field Factory on-Ground Approach

The Amurad-system (Fig. 57.30), developed by the Kajima Corporation, is a way of construction based on the idea of after the first floor is built (which is the top floor), it is pushed up one floor at a time with the aid of large hydraulic cylinders. The plumbing, electrical and mechanical equipment and the interior fittings and cladding of the facade then begin. This process is repeated until the building is completed, where the last floor to be built becomes the ground floor. In order to realize the AMURAD System three automated systems were developed for pushing up the whole building, for transporting and assembling and for material handling.

57.4.3 Robotic Deconstruction and Robotic Recycling

Controlled deconstruction supported by robotic systems can be combined with component reuse systems since some elements such as structural steel have long life spans, and total recycling (i.e., scrapping, melting and recasting) consumes large amounts of energy. In a component reuse system all structural building components are accepted as trade-ins. Therefore, the deconstruction process comprises a reversed version of the construction process, which if it is based on industrialized fabrication, all deconstructed parts and elements could be directly reintroduced into the fabrication systems. The DARUMA system by Kajima Corporation (Fig. 57.31) enables such a controlled deconstruction process. Deconstructed structural steel elements are transported to special dismantling factories just-in-time

Fig. 57.31a,b Systemic and automated floor-by-floor building deconstruction, Kajima, DARUMA System, Japan (a) early deconstruction phase; (b) later deconstruction phase

and just-in-sequence, where the old joints and finishes can be dismantled under factory conditions and fed into advanced reuse cycles. Modularized and standardized structural units can be inspected and renewed and then equipped with new finishes according to each customer's needs. *Component Reuse* systems could be connected to Advanced Construction ERP Systems and companies could match customers who want to sell their modular building for reuse and customers willing to buy reused building modules for further customization. Renewed building components are reorganized and customized in the factory and transported to other building sites. A combined system of controlled deconstruction and component reuse saves large amounts of materials and energy.

By adopting integrated industrialization processes the construction industry would have the chance to address all parameters relevant for sustainable economic, environmental and social development. Innovative industrialization-oriented architectural design structures, appropriate modularization and standardization of building structures, logistics, equipment and

Fig. 57.32 (a) Teleoperated demolition robot (courtesy Brokk AB); (b) water-jet demolition robot (courtesy Conjet AB)

processes, could serve as a fundamental integration framework. Customized prefabrication could further be able to supply construction sites with individualized elements. Hyper-flexible robotic systems could support a limited amount of trained workers to perform positioning, joining and finishing operations. Construction ERP systems could support organization as well as a lean and demand oriented construction based on just-in-time and just-in-sequence resource supply mean-

while locally based factories grant identity and reduced logistic effort. Moreover integrated industrialization would not only be limited to the fabrication but also link systems of controlled deconstruction and component reuse to a network for continuous resource circulation.

In addition to fully automated deconstruction systems, a number of teleoperated demolition robots have been widely adopted in the construction industry. Two examples of these are shown in Fig. 57.32.

57.5 Currently Unsolved Technical Problems

A recent study found that the US construction industry does not realize approximately 15 billion US dollars per year in potential savings due to inadequate interoperability related to information exchange and management practices [57.62].

57.5.1 Interoperability

Although the lack of interoperability between the various information systems used in construction is a significant source of inefficiency for the industry, it is also a roadblock to the use of automated systems in construction. Automated systems need electronic information on past, current, and/or projected future states of a construction project to function efficiently.

For example, in order for a robotic crane to pick a steel beam from the site and deliver it to its target location, the robot must be able to know that the steel beam has been delivered to the site, as well as its current position and orientation. While information on the current inventory of parts on a site may be available on paper, it is rarely available electronically unless someone enters it manually into some computer system, which in turn may not be compatible with other systems used in that project. In many of the examples of automated construction technologies presented in this chapter, custom electronic databases and/or data formats have to be devised to demonstrate the robot's operation. In some cases, the electronic information had to be entered manually from paper into a computer for the robot to work correctly.

In addition to information exchange and management, many of the measurement instruments and sensors used in construction are not interoperable. This problem is not limited to the construction sector but is a relatively large problem in many robotic applications where different types of sensors are used. Several efforts are underway to make sensors interoperable [57.63] and construction equipment in general [57.64], but the issues have yet to be resolved.

57.5.2 Structural Connection Systems

Traditionally, structural member connections in construction have been designed for human installation. Whether using bolted, welded, or other types of connections, manual labor is usually involved in guiding the mating parts together and in establishing the connection.

For example, in structural steel erection, workers perched on the structure typically guide a crane operator through visual or auditory cues in order to maneuver a steel beam (or column) into place. The workers must then physically manipulate the beam in order to align corresponding surfaces for bolting or welding. Once the correct beam pose has been achieved, it must be maintained while the workers temporarily fasten the beam to the structure. The workers then release the beam from the crane and permanently fasten the beam to the structure at a later stage.

For automated (or robotic) construction to work, new connections that are more amenable to automation

Fig. 57.33 A drop-in, shear-load-only, steel connection

Fig.57.34a,b A piping and electrical drop-in connector shown (a) disassembled and (b) assembled

must be designed. These connections need not mimic traditional, human-installed connections, but should be optimized for use with robots instead. For example, the Lehigh University Advanced Technology for Large Structural Systems (ATLSS) Center designed a gravity-load-only shear steel connector [57.65] back in the early 1990s that is more suitable for automated construction (Fig. 57.33). This type of male–female connector for automatic assembly of building modules allows, together with an adequate control strategy, small tolerances, which permit assembly by automatic cranes [57.66].

An example of a nonstructural connector that is more amenable to automation is the piping and electrical connector developed for the FutureHome project, shown in Fig. 57.34 [57.21, 67].

Although automated welding has been applied in some limited form in construction, it is generally used to replace manual welding without changing the design of the parts being welded. In other words, no significant change in the way in which construction components are designed has occurred as a result of automated welding. Moreover, apart from a few examples of automated welding applied at the construction site, most of the other limited applications are done at the component fabrication facility.

57.5.3 Tolerances

Specifications for tolerances in the construction sector exist for most types of construction, however, they are not always achieved in practice [57.68]. For example, it has been stated that one of the biggest sources of problems in structural steel erection in the US is that fabricated pieces are often out of tolerance, and that this is only discovered during installation at the construction site [57.69]. However, since the finished facility must meet the design tolerances before it is accepted, this shifts the burden to workers and supervisors during construction. The workers are expected to handle problems as they come up rather than expect all fabricated construction components to be within tolerance. Since most construction projects are under tight schedules, it is often preferable to fix these kinds of problems on site

rather than wait for replacement components to be fabricated and delivered.

However, tolerance problems are not all due to fabrication errors. Installation problems are also responsible for out-of-tolerance problems, for example, anchor rod installation has been an area of concern for structural steel erection. (Anchor rods (or bolts) are the connection interface between the concrete foundation and the structural steel columns. The rods are usually installed by the concrete foundation crew before the concrete is dry.) The situation of anchor rod patterns that do not match the hole patterns in a mating column is an identified problem in construction [57.26, 70].

Given the relatively loose achievable tolerances in construction, the application of robotics in construction faces an uphill battle. This, in addition to the unstructured nature of the construction site environment, requires that robots either be highly intelligent in order to correctly interpret and react to their surroundings or to be human assisted. However, site structure and tolerances are expected to improve as pressures to reduce costs and improve productivity continue to rise. Improvements in site organization and construction tolerances have already been proved to be achievable in a few cases, as has been demonstrated in Japan [57.71]. However, the economic case for these demonstration projects has yet to be made.

57.5.4 Power and Communications in the Field

Unlike manufacturing environments, in which specially designed factories are outfitted with the necessary power and communications installations, a construction project often begins before such resources have been installed at the site. Therefore, robots with large power requirements that need to communicate with supervisory systems located off site would be challenging to implement without significant added cost.

Although communications technologies have advanced significantly in the last few decades, it is still considered difficult to maintain a reliable local-area network at a construction site and to connect that network to the Internet. The use of cellular telephones

with a press-to-talk (the digital version of the traditional two-way radio communication method) feature has largely replaced the traditional two-way radios that also revolutionized on-site construction communications. However, in order for construction sites to become more automated, reliable interference-free high-bandwidth networks must be able to carry data transmission between sensors, machines, and supervisory systems.

57.5.5 Sensing

Field measurements are an integral part of the construction process. The *tape measure* and the *transit* have been used in construction for decades for measuring distances and angles, respectively. However, construction measurements are not limited to distances and angles, but can also include measurements of installed quantities, percentages of completion of activities, and so on. All of these measurements are necessary to be able to lay out the site where a facility is to be built,

to measure the conformance of the as-built facility to the intended design, and to monitor safety, productivity, and progress.

In the past few decades, more advanced means of making measurements on construction sites have come into play. These include (but are not limited to) total stations, [GPS](#), indoor [GPS](#), ultra-wide band, laser scanners, ground-penetrating radar, equipment and structural health monitoring sensors, concrete maturity meters and radio frequency identification [57.72–84]. These technologies, as well as others that have not yet been adopted in the construction industry, are crucial for enabling more automation and robotics in construction. Nevertheless, despite all of these advances in technology, one of the biggest challenges for implementing robotics at the construction site is to be able to provide accurate and up-to-date information to the robots about where everything is and what other equipment are doing. This challenge will eventually be solved by the introduction of more sophisticated sensing and perception systems.

57.6 Future Directions

As previously discussed, developing new methods for collecting, processing, analyzing, and communicating construction information is a significant area of construction automation research, and will dominate near-term efforts. As this construction information becomes more readily accessible, automation of processes can be enabled directly from the combination of design information and current site status that is accurately captured and shared. Resource tracking will become ubiquitous and just-in-time delivery of needed materials and equipment will happen throughout the site.

Advances in mobility (humanoid robotics, smart cars, legged locomotion, etc.) will enable ever more

automated material handling on the job site. These advances will require better control systems for the construction robots that can provide high payload and good positioning accuracy. The increased use of robots at the construction site will also drive research into safety systems for construction robots working around human workers and other machines.

Perhaps most important, more extensive automatic design systems will enable more prefabrication of building components and new methods of assembling those components on site, which in turn will provide the promise of faster, better, and cheaper construction robotics first envisioned in the 1980s.

57.7 Conclusions and Further Reading

The application of robotics to construction has yet to catch up with other industries such as automobile manufacturing. Construction presents a unique challenge for robotic applications. The construction environment is cluttered, unstructured, and teaming with human workers. In addition, construction processes are usually labor intensive and have to accommodate wide margins of error in the constructed facility. The application of robotics in construction to date has been limited to commercial teleoperated and programmable machines. Autonomous or semiautonomous machines are currently mostly limited to research projects within var-

ious nonconstruction organizations. With the increase in competition throughout the global construction market, construction companies are on the lookout for ways to improve productivity, quality, and safety. The use of automation and robotics is one answer that the industry is slowly turning toward. However, before these potential solutions can be successfully applied, much work is needed to improve construction tolerances, develop standards, and achieve real-time site status monitoring.

The International Association for Automation and Robotics in Construction holds an annual conference (the International Symposium on Automation and

Robotics in Construction) at which researchers can present the latest developments in the field. The proceedings from this conference hold a wealth of information on the state of the art of the field and are accessible to the general public through IAARC's website (www.iaarc.org).

There are several journals that publish articles on various aspects of automation in construction.

Most notable of these are *Automation in Construction*, *Computer-Aided Civil and Infrastructure Engineering*, the *Journal of Computing in Civil Engineering*, and the *Journal of Construction Engineering and Management*. In addition, some journals publish special editions on robotics in construction. Some examples are *Autonomous Robots* and the *Journal of Advanced Robotic Systems*.

58. Robotics in Hazardous Applications

James Trevelyan, William R. Hamel, Sung-Chul Kang

Robotics researchers have worked hard to realize a long-awaited vision: machines that can eliminate the need for people to work in hazardous environments. Chapter 60 is framed by the vision of disaster response: search and rescue robots carrying people from burning buildings or tunneling through collapsed rock falls to reach trapped miners. In this chapter we review tangible progress towards robots that perform routine work in places too dangerous for humans. Researchers still have many challenges ahead of them but there has been remarkable progress in some areas. Hazardous environments present special challenges for the accomplishment of desired tasks depending on the nature and magnitude of the hazards. Hazards may be present in the form of radiation, toxic contamination, falling objects or potential explosions. Technology that specialized engineering companies can develop and sell without active help from researchers marks the frontier of commercial feasibility. Just inside this border lie teleoperated robots for explosive ordnance disposal (EOD) and for underwater engineering work. Even with the typical tenfold disadvantage in manipulation performance imposed by the limits of today's *telepresence* and teleoperation technology, in terms of human dexterity and speed, robots often can offer a more cost-effective solution. However, most routine applications in hazardous

environments still lie far beyond the feasibility frontier. Fire fighting, remediating nuclear contamination, reactor decommissioning, tunneling, underwater engineering, underground mining and clearance of landmines and unexploded ordnance still present many unsolved problems.

58.1 Operation in Hazardous Environments: The Need for a Robotics Solution

Routine work in hazardous environments presents many challenges for robotic devices that depend on both the tasks and the hazards. Hazards may be present in the form of temperature extremes, radiation, toxic fumes

and materials, potential explosions, risk of electrocution, the absence of breathable air in space, and the high pressure of underwater environments. When the magnitudes of one or more hazards reach the point

that human exposure would either represent a direct threat to life or unacceptable long-term health consequences, some form of remote operations that separate humans from the hazards must be employed. A long-extant example of such operations is the nuclear industry where telerobotics has become a well-established technique for operations in environments with high levels of nuclear radiation. Many of the technical roots of modern robotics technology can be traced back to nuclear remote handling manipulators and support systems. Remote handling and operations concepts using engineered systems that allow humans to perform hazardous work while staying in a safe environment have evolved since the 1940s. Today, such remotely operated systems are widely used and recently they have become routinely used in explosives disposal, security operations, handling of dangerous biological materials, and routine inspection of industrial systems such as power lines, substations, sewers, piping systems, pressure vessels and many others.

A remote handling system will generally involve subsystems for mobility, manipulation, tooling, sensing, and human-machine interfacing (Fig. 58.1). Nominal operations involve the collective workings of these subsystems to accomplish remote operational goals. Any remote handling system will eventually experience some aspect of off-nominal operation that may be the result of unexpected environmental events or system malfunctions. The fundamental idea is to connect the human operator to the remote environment via a power and signal infrastructure that allows effective operation in the remote environment: mechanized devices and sensor systems that allow the human's perception and action capabilities to be *projected* into the hazardous environment to perform remote operations. The more

realistic this projection, the more natural and effective the human remote control will be.

Because of their inherent complexity and the very nature of remote operations, operator training is a major challenge that requires the use of simulations and cold testing facilities that provide operators with comprehensive and realistic training. Such training will typically encompass all aspects of nominal and anticipated off-nominal operations.

Remote handling systems themselves will eventually experience equipment failures. Remote recovery/maintenance/operation of failed remote systems must be an integral part of their basic design and operational features. Hardware/software features must be provided for the analysis of, recovery from, and correction of problems.

Robotics researchers have worked hard to realize a long-awaited vision: machines that enable people to perform routine work without exposure to hazards. In this chapter we review progress and some of the current and future challenges that lie ahead for researchers.

Technology that specialized engineering companies can develop and sell without active help from researchers marks the frontier of commercial feasibility. Just inside this border lie teleoperated robots for explosive ordnance disposal (EOD) [58.1, 2] and for underwater engineering work. Even with the typical tenfold disadvantage in manipulation performance imposed by the limits of today's *telepresence* and teleoperation technology, compared with human dexterity and speed, robots can often offer a more cost-effective solution. Naturally, if people need to wear protective suits to protect them from hazards, their endurance and dexterity will be restricted.

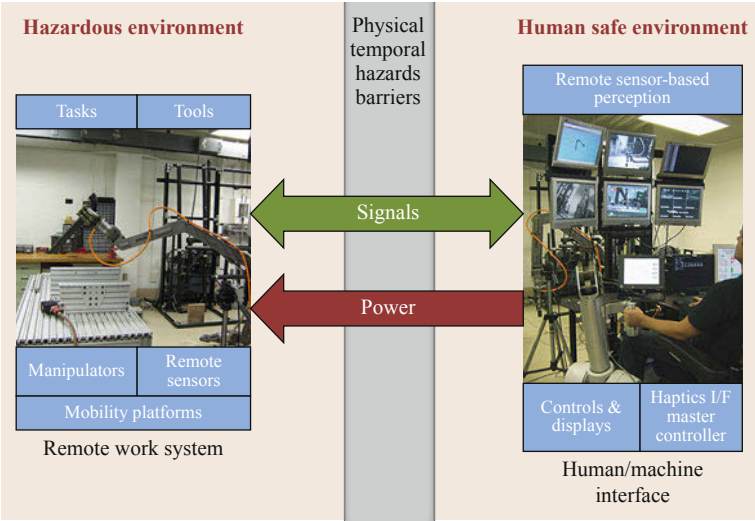

Fig. 58.1 Basic subsystems of a remote handling system

Fig. 58.2 Remotely operated vehicles designed for underwater engineering work, demonstrating an ingeniously simple technical arrangement compared with conventional free-swimming vehicles. (courtesy of Total Marine Technology, Australia)

Ingenuity stimulated by commercial incentives can greatly reduce the operating costs of remotely operated equipment. Figure 58.2 illustrates the elegant simplicity of the NOMAD remotely operated vehicle (ROV) that pulls itself deeper with a simple electric winch. It can be left in place overnight or during rough weather. Free-swimming robots are much more complicated and expensive and have to be hauled out of the water when not under active control.

Limited autonomy or autonomous operation for a restricted time can relieve operator fatigue and allows unmanned aerial vehicles (UAVs, often referred to as drones) to fly extended reconnaissance missions with occasional precision weapon delivery. Such missions would be too hazardous or too politically sensitive for manned aircraft.

Even after the first decade of the 21st century, with 60 years of remote operating experience, most haz-

ardous applications still lie far beyond the frontier of commercial feasibility. Fire fighting, remediating high-level nuclear contamination [58.3], reactor decommissioning, tunneling, underground mining, and most landmine and unexploded ordnance problems still present many research challenges. Most attempts to use first-generation mine rescue robots reported in the press in 2000 and 2001 have merely created distractions for the people who regularly have to risk their lives saving their trapped colleagues (e.g., the Australian Numbat robot [58.4]). The Fukushima Daiichi nuclear reactor disaster triggered by the March 2011 tsunami that devastated parts of Japan serves as a reality check on our capacity to use robots effectively for hazardous tasks. Beyond the carefully engineered environments that characterize the nuclear material handling industry, the disappointing performance of several robots has demonstrated just how far we still have to go.

58.2 Applications

Potential applications of robotic systems in hazardous environments encompass an extremely wide spectrum, limited only by human imagination. The solutions for these different environments are equally diverse. In general such applications involve unique challenges associated with the uncertainty and unstructured nature of the associated tasks. In this discussion, two application areas that are very different have been selected

to give the reader a deeper sense of technology evolution, accomplishments, and remaining challenges. The first application we will discuss is landmine eradication, sometimes referred to as demining, a current application domain with humanitarian importance and extremely difficult and hazardous outdoor conditions. The second application area is hazardous nuclear and biological material handling, a decades-old industry

that has strongly influenced many aspects of robot manipulation and mobility research and development. We conclude this section with a brief discussion on the lessons learned from the Fukushima Daiichi disaster, lessons that help to strengthen our argument that we are still at a very early stage of development in robotics for routine operations in hazardous environments.

58.2.1 Eradicating Landmines

Efforts to construct a practical robotic device to help with landmine clearance have met with only limited success. While remote control technology has enabled some existing machines and vehicles to be used in hazardous situations, we are still a long way from achieving reliable robotic mine clearance. It is instructive to understand why many expectations turned out to be hopelessly optimistic.

Landmines, a simple type of victim-activated explosive device, were used extensively in Europe and North Africa during the Second World War between 1939 and 1945. Extensive clearance operations in 1945 and 1946 removed nearly all of the landmines then in use [58.5, part 1, pp. 15–25].

Landmines were used extensively in subsequent decades. Along with antipersonnel cluster bombs, they caused extensive civilian and military casualties in Vietnam and Cambodia from the 1960s onwards. However, it was not until their widespread use in Afghanistan,

Angola, Cambodia, and several other countries in the 1980s that they were recognized as a major humanitarian problem. Landmines blocked aid efforts needed to rebuild communities following civil conflicts.

The Red Cross and the International Campaign to Ban Landmines (ICBL) successfully promoted a ban on the use of landmines that came into effect in 1997 as the Ottawa Treaty. The knowledge that thousands of children were losing their legs, even their lives, motivated hundreds of researchers to develop new technologies to help eliminate this threat. By 2000 ICBL estimated that over 80 countries were affected by landmines and other explosive remnants of war such as cluster bombs. Although several countries that have not signed the Ottawa Treaty still have extensive stocks of landmines, the treaty has been effective in restricting the use of landmines more through peer pressure. A few countries and several non-state actors continue to deploy landmines. However, other explosive remnants of war such as cluster bombs and other munitions have become, yet again, an increasing problem in Iraq, Afghanistan, Libya and Syria.

There are several basic types of landmines and unexploded ordnance (UXO) that continue to cause problems in many countries.

Antipersonnel (AP) blast mines, made predominantly of plastic with small metal firing pins and detonator cases, typically contain between 20 and 100 g of explosive (Fig. 58.3). These mines only cause extensive injuries when they detonate within a few centimetres of a person. Typically they lie buried just below the ground surface and are activated when the victim steps on top of the mine. Shattered fragments of bone pass through the flesh of the leg at high velocity. If the victim survives long enough to reach hospital, amputation above or below the knee usually saves his or her life but the victim will need prosthetic legs, replaced at regular intervals.

Antipersonnel fragmentation mines contain similar quantities of explosive with a thick metal case that breaks into high-velocity fragments when the mine explodes just above the ground surface. Older fragmentation mines were mounted on posts; some varieties lie buried but jump into the air when activated and explode at waist height, killing or seriously wounding victims up to 200 m away. These mines are much easier to detect so they are often protected by nearby antipersonnel blast mines to deter theft.

Anti-vehicle (AV) or anti-tank mines (ATs), made predominantly of plastic with small metal firing pins and detonator cases, are large versions of the AP blast mine and typically contain 5–10 kg of explosive. Some have a thick metal plate on top that can penetrate 50 cm of armor plate on the underside of a tank. These mines cause significant damage even to mine-resistant vehi-

Fig. 58.3 Antipersonnel fragmentation mine (left) and buried blast mine (right)

cles which have blast-resistant hulls, offset wheels, and additional protection for occupants.

Air-dispersed munitions such as cluster bombs (CBs) were not intended to be victim-activated. Several hundred are released at one time from a single canister and they are designed to explode on impact with the ground. Typically between 5 and 25% fail to explode immediately and lie in a partially triggered state either on or just below the ground surface. Some will detonate in response to electromagnetic fields from metal detectors, and others will detonate with the slightest movement. Most explode like powerful fragmentation mines with a lethal radius of up to 200 m.

Improvised explosive devices (IEDs), often in the form of roadside bombs, are increasingly used by insurgent groups fighting organized military forces (asymmetric warfare). They are often made from large UXOs fitted with remote controlled detonators [👁️ VIDEO 572]. Ironically the UXO is often unintentionally donated by the same organized military forces who become the targets of these devices. IED detection and clearance has become one of the highest priorities for military robotics research.

Evolution of Landmine Clearance Techniques

Removing landmines is usually both laborious and hazardous. It is important to distinguish between humanitarian mine clearance and military mine clearance methods (sometimes called *breeching*). Military mine clearance has to work fast, in all conditions (even under fire), and therefore it is unrealistic to aim for 100% clearance. In humanitarian operations there is less time pressure and work can be suspended in unfavorable conditions, and the aim is 100% clearance. Since the 1990s, the expectation in industrialized countries of low casualties from military operations often demands very high clearance standards even for urgent military operations.

Humanitarian mine clearance typically starts years, perhaps decades, after the mines were laid. The mines lie buried or hidden from view. They deter people from entering the land so vegetation often grows thickly (Fig. 58.4). Drainage systems rapidly become clogged, denying access in wet conditions.

The traditional *manual* method for removing landmines has been to use a metal detector to locate metal fragments close to the ground surface and then to carefully check each metal fragment to see if it is associated with a mine or explosive device [👁️ VIDEO 571]. Any tripwires and vegetation have to be removed, with great care, before a metal detector can be used. In many areas deminers have to investigate hundreds or thousands of metal fragments for every mine found. Manual mine clearance also requires careful organization and

Fig. 58.4 Typical ruined house overgrown by vegetation in a village in northern Croatia, possibly containing mines or booby traps. The entire village population was forced to leave in 1991 and the houses were looted and intentionally severely damaged. Vegetation problems like this must be taken into account in considering practical mine and UXO clearance devices. August 1999 (courtesy of J. Trevelyan)

marking of the ground to ensure safety and thorough clearance. Currently it is still the method that guarantees the lowest risk of residual mine contamination but it is expensive, typically costing US\$ 1–5 /m².

Armored mine clearance machines using hammers mounted on the end of rapidly spinning chains (flails) first appeared in the 1940s but have not been able to neutralize mines with sufficient reliability for most humanitarian applications [58.6].

In the late 1990s commercial mine clearance organizations operating in thick vegetation in Bosnia Herzegovina and Croatia realized that flails spinning just above the ground could rapidly remove vegetation and trip wires to prepare the ground for manual clearance, often assisted by mine detection dogs. Clearance costs have been reduced by up to 80% (particularly in thick vegetation) using different combinations of machines, detection dogs, and manual clearance.

Ground milling machines use metal drums studded with hard cutters that shred buried objects. They require more power than flails but can operate with greater levels of reliability (Fig. 58.5). Both flails and ground milling machines have been extensively used in Croatia to recover large areas of formerly productive agricultural land. Both kinds of machines can withstand a limited number of AT and moderate-size UXO explosions before main bearings and other components need to be replaced [👁️ VIDEO 574, 👁️ VIDEO 575, 👁️ VIDEO 576, 👁️ VIDEO 577]. Several of these machines have remote operation capabilities (Fig. 58.6).

Naturally, machines operate best on flat or gently sloping ground, which is also the land that is most valuable for agriculture and human habitation. Thick forest

Fig. 58.5 Flail machine using hammers on the ends of spinning chains to clear vegetation and tripwires. This machine will also detonate a proportion of buried mines (*inset*) (courtesy of Scanjack AB, Sweden)

Fig. 58.6 Bozena teleoperated demining vehicle (courtesy of Way Industry, Slovakia)  **VIDEO 574**

and mountainous terrain still requires traditional manual clearance and, in most countries, will not be cleared of mines for a long time, if ever.

Mechanized clearance methods continue to evolve with improvements to machines and techniques. Machines can be used for survey, risk assessment, and risk reduction tasks to help determine the need for more expensive manual clearance methods. Mine action programs are gradually shifting from an emphasis on total clearance in the 1990s to one of progressive prioritized risk reduction involving a series of measures including high-security fences, mechanized survey and risk reduction methods, and selective manual clearance [58.5, part 4]. Protective measures applied to agricultural machinery offer cheaper alternatives in low-AT-risk areas [58.7].

Evolution of Demining Research Priorities

Technological development in landmine clearance from within the demining community has mainly been driven by the search for improved productivity. Many of the comments in this section are based on numerous discussions with experienced demining personnel who have tried new technologies in the field. References have been cited where further detailed written information is available.

In the mid-1990s there was the expectation that, with sufficient research, advanced technology detectors could replace eddy-current metal detector technology that had been in use since the 1940s. Metal detectors also react to metal fragments in the ground. A detector that could confirm the presence of explosive, it was thought, would save having to investigate all these false alarms. The most promising line of research seemed to be data fusion: combining signals from a metal detector, ground-penetrating radar, infrared detectors, thermal neutron detectors, and even acoustic detectors. Astute observers at research conferences have pointed out that these signals are often well correlated, even in the presence of false alarms: producing a reliable detector was going to be hard work. Their forecasts turned out to be very accurate. Only one such detector is currently in operation: the handheld standoff mine detection system ([HSTAMIDS](#)) detector used by US military forces in Afghanistan employs a combination of ground-penetrating radar and eddy-current metal detection. Little information on its effectiveness has been released and no independent trials have been reported.

Experienced research groups report that ground-penetrating radar requires accurate alignment of the detector with the ground surface (to eliminate ground surface returns) and also with the target center point to enable the target to be characterized reliably. If the principal metal component of the landmine coincides with its geometric center, a common feature of minimum metal mines, the metal detector can be used for alignment. However this is not always the case and one cannot guarantee the absence of other metal fragments near the mine. Ground-penetrating radar provides confusing returns in very dry or very wet conditions and is also susceptible to false alarm indications from underground discontinuities such as stones, sticks, animal burrows etc. Publishers mostly downplay these difficulties and prefer only to report positive results, not false negatives. These issues only emerge from discussions with developers who have seriously evaluated technology in field conditions.

The major performance improvements in sensing have been obtained by compensating eddy-current metal detectors for soil magnetization, enabling them to work in a much wider range of soil conditions. Improvements in sensitivity can help with minimum metal mines but can also result in a large number of false alarms from smaller metal fragments. Metal detector arrays have been fitted to vehicles to speed up clearance of paved areas and roads [58.8].

By the late 1990s slow progress with sensors had become more apparent and research priorities after 2000 gradually turned to mine detection dogs and large demining machines.

The Afghanistan Mine Action Center (MACA) started using mine detection dogs around 1993 but it was not until 1998 that this program was running effectively. There were several difficulties. The first challenge was that close association between humans and dogs was socially unacceptable in Afghanistan. The second challenge was to devise ways to use dogs and manual mine clearance in an effective combination providing reliable clearance with high productivity. This was much the greater challenge, but by 1998 the cost of clearance using dogs was around one-third the cost of manual clearance. It was then that the problems started to appear: the occasional missed mine that could not be explained by lack of organization or failure to follow procedures. At the same time, carefully controlled trials of mine detection dogs in Bosnia had returned highly variable results. On several occasions dogs had walked past blocks of trinitrotoluene (TNT) lying almost visible in the ground. Yet, at the same time, a number of commercial demining agencies were routinely declaring land free of mines using similar dogs. In late 1999

the Bosnian Mine Action Center ran a carefully controlled test in which around 80% of the dogs failed to achieve the required performance standard. The results were hotly contested at the time and the international community organized a systematic trial of mine detection dogs through the Geneva International Centre for Humanitarian Demining (GICHD).

By 2001 it was apparent that there had been little scientific research on the fundamental physiological mechanisms that enable dogs to locate sources of explosive vapor. Dogs had been able to find mines using explosives (such as high melting point explosives like HMX) with vapor pressure far below measurable detection thresholds. The mechanism by which TNT vapor and its breakdown products reach the ground surface was the subject of considerable scientific debate. By 2003 a systematic trial in Afghanistan, scientific studies at SANDIA Laboratories in the USA and in Scandinavia, explosive trace detection studies with dogs at Auburn University, and several other investigations provided some insight into this problem for the first time [58.9]. However, the precise physiological mechanisms for canine explosive detection remain unclear, especially for lower-vapor-pressure explosives. We still do not know for sure whether dogs are reacting to vapor, minute particles of explosive suspended in the air, biochemical breakdown products, or a combination.

In 2003 a US company, NOMADICS, demonstrated the FIDO detector, the first that could reliably measure the presence of TNT vapor with greater sensitivity than a highly trained dog. However field trials showed that TNT vapor could be detected everywhere in a mine contaminated area. An explosive vapor sensor was just the beginning of the story and warns of a complex cognitive task ahead in using the patterns of variation to localize targets.

By 2004 the international community realized that the early confidence in a breakthrough resulting from advanced sensor technology, demining machinery, and mine detection dogs had been misplaced. GICHD commissioned a detailed study of manual demining to see whether productivity improvements could be made. A systematic series of trials were conducted in Africa to determine the effectiveness of several innovations such as magnets and rakes. The final report, issued in 2005, revealed that greatly improved productivity was possible but would depend more on improving contracting arrangements, management, and training than technology.

The New York attacks in September 2001 fundamentally changed research priorities. Removing unexploded ordnance, particularly cluster bombs, became the top priority for the next 12 months in Afghanistan

(Fig. 58.7). Since then the deteriorating security and political situation in Afghanistan has focused mine clearance agencies more on maintaining security for their own workforce than trying to improve productivity and safety.

Resistance to the US and international occupation of Iraq and the easy availability of explosives both from former Iraqi armed forces and unexploded ordnance from US military operations led to the proliferation of improvised explosive devices (IED) to attack organized military forces and police. These have now become the main threat and the focus for much of the funding, and operational and research expertise formerly available to support mine clearance operations. This development has also placed ordnance disposal teams at the front line for the first time, rather than working in well-protected secure areas. Iraqi insurgent groups attack ordnance disposal teams both because they are attempting to disarm some of the insurgents' most effective weapons and also because they remove the main sources of explosives available to insurgent groups.

Improvised explosive devices, when detected, are often investigated and neutralized using remotely operated robots. While there are non-destructive methods to neutralize IEDs, the fastest method usually involves placing a small shaped charge device close to, and accurately aligned with the device. Operational details remain confidential to reduce the risk that IEDs will be modified to defeat current neutralization methods.

Paradoxically it is this development that has enabled robotics to make a greater contribution to the problem

by through improvements in remote manipulation technology. These improvements come more in the form of low-cost commercial off-the-shelf components (mobile platform, motors, TV cameras etc.) than from fundamental research advances. Improvements are still being made: improved remote manipulation, blast survivability, operator interface improvements, and mobility improvements have all contributed significantly to performance and reduced operating costs.

Advances in Demining Robotics Research

In a brief survey it is not possible to mention every contribution. We have attempted to provide a sample of research reports that illustrate the main achievements and we present brief technical discussions on mobility and manipulation dexterity.

Teleoperation remains the only robotics technology that has been used in practical application in field conditions [58.10–12], even with devices such as iRobot and machines such as MineWolf. Robotics research has not yet been able to make a significant contribution to mine and unexploded clearance work. However, the problems posed by landmine clearance have stimulated new research results that could have other applications.

Robotics researchers started their efforts in the early 1990s, for example, Havlik and Trevelyan independently proposed suspended cable robots to work in minefields [58.13]. However, both have later argued in favor of alternative solutions [58.10, 14].

Nicoud [58.15] wrote one of the first surveys exploring the possibility of using robotics technology for landmine clearance. Developments in robotics research since the mid 1990s have been motivated both by a genuine desire to help combat a serious humanitarian issue and also by a desire to find a justification for more fundamental research. However, most researchers still have not learned lessons from the field such as the need to remove vegetation and the variety of situations in which deminers find themselves [58.16].

One of the most prolific research areas justified in part by humanitarian demining problems has been path planning for autonomous agents [58.17]. Probabilistic approaches were explored by [58.18]. Some researchers have proposed multiple robot solutions, even *swarms* of robots [58.19] and so-called *immune systems* [58.20]. Autonomous search and mapping algorithms have also been explored [58.21], including even three-dimensional (3-D) search techniques for locating underground chemical sources [58.22].

Landmine clearance has also stimulated developments in autonomous robot vehicles, with many examples in the literature [58.23]. Tracked vehicles have been proposed for working in rubble and built environments [58.24]. Walking vehicles have been proposed,

Fig. 58.7 Unexploded BLU-97 cluster bombs in Afghanistan early in 2002. Two of the small yellow canisters with parachutes still attached lie visible in the foreground. Others lie in the houses in the distance. Some may lie up to 40 cm below the ground surface. Some can detonate when a metal detector or mobile phone is used nearby. These devices have a kill radius of 200 m and can sometimes be set off by a strong gust of wind. They readily attract the curiosity of children (courtesy of G. Zahachewsky and N. Spencer)

particularly for difficult terrain in countries like Bosnia and Afghanistan [58.25] even to the extent of examining how damaged robots with missing legs could extricate themselves from a mined area [58.26].

The desire to keep human operators away from the risk of handling unexploded ordnance has stimulated research on artificial hands and telemanipulation [58.27]. Purely mechanical devices have also been explored [58.28]. Several researchers have provided detailed results of tests with manipulators mounted on autonomous vehicles [58.29] (Fig. 58.8).

Robotics solutions have also been proposed partly to overcome the limitations of handheld sensors such as ground-penetrating radar. A robot manipulator can control the motion of the sensor so much more precisely, opening the possibility of synthetic aperture techniques for both metal detection and radar [58.30].

Military research agencies in the United States, Australia, Britain, and Canada devoted large research budgets to the problem of road clearance since AT mines and IEDs accounted for a large proportion of military casualties in Somalia, Bosnia, Iraq and Afghanistan. Insurgent forces had demonstrated that they could bring organized military forces to a complete standstill overnight simply by laying anti-vehicle mines in a few road potholes. With most roads in poor condition there was no easy way to detect that the mines had been laid. Insurgents would typically use mines to stop leading vehicles in a convoy in order to increase the effectiveness of an ambush.

Most research teams proposed one or more vehicles carrying multiple sensors including ground-penetrating radar, metal detector arrays, passive and active infrared, and even some acoustic arrays. Some sensor arrangements were designed to look forward sufficiently far to allow the carrier vehicle to stop before reaching a mine. Others were to be carried by lightweight remotely controlled lead vehicles. Military planners calculated that search speeds of ≈ 30 km/h would be required to be able to check roads daily in time for supply convoys to use the roads in daylight hours. Many different arrangements have been reported [58.31]. Other teams proposed teleoperated devices for landmine and explosive ordnance detection and neutralization but few anticipated the requirement to operate under armed attack. Typical requirements envisaged secure rear area mine clearance in combat situations and peace-keeping on roads and tracks [58.32] or force protection roles [58.33]. Most of these efforts were initiated in the late 1990s but by 2005 it had become apparent to military planners that vehicle protection rather than mine detection was a more practical solution. Much of today's vehicle protection technology originated in southern Africa with further development in Australia,

Fig. 58.8 Gryphon experimental robot on trial in Cambodia (after [58.29] courtesy of S. Hirose)

the UK, and other countries, stimulated in part by South African expatriates.

One way to reduce the distance between researchers and field problems, at least in terms of geographic distance, has been to promote research in landmine-affected countries such as Sri Lanka and Colombia [58.34]. However this is not easy. Most countries affected by landmines have been disrupted by social conflict and destabilization that led to the military conflicts in which landmines were used. This makes it difficult for local people to create sufficient economic and physical security for researchers to pursue their work.

Future Prospects for Robotic Demining

What are the challenges for robotics researchers working on landmine clearance and other hazardous applications in the future?

We need further advances in mechatronics design, sensing, and accurate understanding of the problems to be solved using robots.

The best starting point for research is to witness people undertaking hazardous work in several different situations. Nuclear accidents, mine disasters, and burning buildings are usually off-limits to researchers. However, mine clearance operations are readily accessible in many countries. Though many researchers think a visit would be far too hazardous, there is no better way to appreciate the practical difficulties involved. Photographs taken at mine clearance operations are available to provide researchers with a web site for reference purposes, partly in answer to this need to understand the practical realities [58.35].

One of the main motivations for robotics researchers has been the perception that mine clearance is a hazardous occupation and that it would be more preferable for robots to be exposed to minefield risks

than human beings [58.36]. While mine clearance is certainly a hazardous occupation it is not necessarily dangerous. Accident records show that mine clearance in Afghanistan in 1998 resulted in about half the rate of injury of the United States forestry industry and about one third the rate of injury for the United States building construction industry per 100 000 working hours. Mine clearance agencies use advanced techniques to improve safety when possible [58.37]. In terms of deaths, demining is considerably less hazardous than mining, construction of building foundations, and especially offshore drilling rigs [58.38, pp. 11–14].

Another motivation for research is to reduce deaths and injuries among local people who have to live with the daily threat of landmines and unexploded ordnance. Again, there are misperceptions of risk. The incidence of death and injury from mine explosions is often very small compared with disease, for example. The main priorities for local people tend to be improvements for water and food supplies, education, sanitation and physical security: landmine clearance is usually a much lower priority and it is often hard to justify significant local resources.

It is also important that robotics researchers intending to contribute to the solution of this problem understand the relatively small size of humanitarian demining operations, which have been funded from a combined international humanitarian aid budget of approximately US\$ 400 million. These programs spend an estimated \$ 20 million annually on all equipment needs. The market for specialized humanitarian demining detectors is therefore very small and manufacturers cannot afford research and development specifically to support humanitarian demining solutions [58.39]. Adapting technology developed for other purposes, such as military equipment or civil engineering construction machinery, is more likely to be feasible.

From 1990 to 2014 there were significant improvement in mine clearance techniques but overall progress is still slow and robotics may well provide the final solution in the long term. There are still opportunities to develop robotic techniques that could ultimately provide the only cost-effective method for finally eliminating this menace.

58.2.2 Hazardous Materials Handling and Operations

The oldest application of robotics-related technology to hazardous environments is various aspects of remote nuclear operations dating back to the beginning of serious work on atomic physics in the early 1940s. This section discusses hazardous materials and operations in the context of nuclear applications and some extrap-

olations to other domains. These applications run the spectrum from low- to high-fidelity manipulation and multiple mobility modes.

In the 1940s, research in atomic physics led to a new era in remote handling as scientists sought to explore the nature of materials involving ionizing radiation. As experiments became more complex, mechanical manipulator systems were created which allowed operators to perform increasingly complex tasks safely behind thick biological shielding  VIDEO 586,  VIDEO 587,  VIDEO 588,  VIDEO 590. These mechanical systems then evolved into electrical systems that allowed larger work volumes to be considered. Incredible engineering achievement occurred in a 15 year period within the Remote Control Division of the Argonne National Laboratory. Even though this era represented tremendous technical achievement, it went further in illustrating the intrinsic complexity of remote operations. The equivalent work performance achieved with sophisticated teleoperated remote systems is poor in comparison to what human workers can achieve with direct contact operations and common tools. Typically, this form of teleoperation (i.e., manual control over a physical distance or barrier) is ten to hundreds of times slower than the equivalent operations performed directly by a human. Remote operations are extremely expensive and time consuming and have been the continual target of engineering improvements over the years.

Many research and development efforts have focused on different avenues for improving the work efficiency of teleoperated remote operations  VIDEO 589. These efforts have included the development of better manipulators, control stations, control algorithms, etc., all intended to enhance reliability and maintainability. In the late 1960s and early 1970s, as digital electronics became more cost effective, interest began to emerge in the integration of automation with teleoperation as a scheme to effectively increase remote operations work efficiency. It was around this time that industrial robot concepts were also introduced. Combining selective automation of specific subtasks with traditional teleoperation offers the potential to reduce labor requirements and to improve the quality of repetitive task executions. This integration of automation with teleoperation became the foundation of what is now termed *telerobotics*. From the 1970s until today, telerobotics has been an active area of research and development in many different domains that include nuclear, space, and military applications. Unlike manufacturing automation, remote operations in hazardous and unstructured work task environments necessitate human-in-the-loop control, or teleoperation, at least as a backup, to assure safe operations. Teleoperation related to hazardous materials

and operations, in the most general sense, involve mobility and the use of manipulators to handle objects and tools to accomplish useful work in predominantly unstructured and uncertain environments.

Over the years, there have been numerous papers, books, and reports written concerning technical challenges, issues, and solutions. Readers will find *Vertut* and *Coiffet* [58.40] and *Slutski* [58.41] provide comprehensive and general information about manipulators and systems  **VIDEO 590**. The performance and design of effective teleoperated systems are strong functions of human factors and *Kraiss* [58.42] and *Johnsen* and *Corliss* [58.43] provide good discussions of key principles. Finally, control system hierarchies and structures are explained in depth by *Sheridan* [58.44]. A final emphasis to all readers would be to fully explore the annals of the American Nuclear Society's Remote Systems Division, later renamed Robotics and Remote Systems Division (**RRSD**). Over the decades, this division hosted numerous topical meetings and workshops on all aspects of remote operations. A starting point is <http://rrsd.ans.org/pages/topicals.html>.

Past Perspectives

Initially, science and experiments involving dangerous radiation levels were accomplished through the innovative use of shielding walls, long-handled tools, and mirrors. As the tasks became more difficult, mechanical arms that could do a better job in emulating human motions were pursued. These ideas represented schemes whereby human sensing and handling capabilities could be more completely *projected* into the remote work environment [58.45]. One of the first challenges that the Argonne group tackled was the development of the mechanical master–slave manipulator. The basic concept was to create a mechanism that would have a master controller side where an operator could provide position and orientation commands to a slave-side mechanism/linkage system that would *replicate* motions and forces in the remote work area. It was felt that force reflection to and from the master and slave systems was essential for the operator's sensory awareness of the task execution. Experimentation has repeatedly verified the significance of both kinesthetic and tactile feedback in performing more complicated tasks [58.46].

Today, master–slave manipulator (**MSMs**) are used around the world in nuclear, biological, and other types of hazardous remote experimentation and operations. (They have also become increasingly used for so-called robotic surgery.) The remote work efficiency of a dual-arm **MSM** with shielded-window viewing is around 5–10 times slower than equivalent direct human contact operations. Because the master and slave sections of

MSM's are mechanically coupled through the metal-tape drive transmission, the physical separation that can exist between the safe operating area and the hazardous remote work area is limited to a maximum of ≈ 10 m. Because of this characteristic and their kinematics, **MSMs** are restrictive in many applications and often have constrained the physical design of remote cells. The Argonne group and others recognized that it would be much better to have the equivalent of a fly-by-wire **MSM** in which the physical separation of the master and slave could be larger. This need led to the development of electrical master–slave manipulators (**EMSs**) that are commonly called electrical servomanipulators [58.47, 48]. Research and Development on the **EMS** began in the late 1940s and continued into the early 1950s.

The Argonne group was at that time limited by the available electrical control technology. Nonetheless, they made noteworthy progress toward integrated systems, as depicted in Fig. 58.9. The prototype system shown is a dual-arm anthropomorphic system with head-aiming remote television viewing and bilateral force reflection. After the Argonne Remote Control Division was disbanded, limited research and development occurred until the 1970s when commercial nuclear power growth was driving a number of research programs in the US, West Germany, France, and Japan. During this time, the programs in the US and France were focused on electrical servomanipulator systems which incorporated emerging microprocessor technology. The Central Research Laboratories model M2 system, shown in Fig. 58.10, was jointly developed with the Oak Ridge National Laboratory and was the first force reflecting servomanipulator system to use distributed digital electronics to implement position–position force reflection with multiplexed serial communications between the master and slave. The

Fig. 58.9 An integrated electrical master–slave manipulator system (courtesy of Oak Ridge National Laboratory)

Fig. 58.10 CRL Model M2 manipulator system performing space truss assembly (courtesy of Oak Ridge National Laboratory)

model M2 system was used over the years to explore remote operations for military, space, and nuclear applications.

The development of the advanced servomanipulator (ASM) followed the M2 in an effort to improve the remote maintainability of the manipulators themselves. This work was one of the earliest modular robotics efforts. The motivation for this work was to reduce maintenance technician radiation exposure and to increase the overall availability of the remote maintenance system. The ASM was designed from the beginning to provide a foundation for telerobotics in addition to effective teleoperation [58.49] (Fig. 58.11).

At the time of the M2 and ASM developments, Jean Vertut and his colleagues in the Commissariat à l'Énergie Atomique (CEA) focused their research on the development of telerobotic functionality for their MA-23 electrical servomanipulator systems. This research appears to include some of the earliest experimental demonstrations of telerobotic functions [58.40]. They called their concept computer-assisted teleoperation and it included both operator assists and robotic teach/playback functions. Operator assists included software jigs and fixtures designed for the improve-

Fig. 58.11 Advanced servomanipulator system (courtesy of Oak Ridge National Laboratory)

ment of the remote operation of tools such as saws, drills, etc.

In the 1980s and 1990s as nuclear power activities began to decline, nuclear remote operations technology was migrated into other areas such as space and the military. Nuclear remote operations experience with teleoperation influenced the Space Shuttle remote manipulator system and the short-lived Flight Telerobotic Servicer program.

In the mid 1990s, substantial interest developed in the application of remote handling systems to deal with problems in hazardous site/facility remediation, such as those associated with defunct nuclear facilities in the US and in Eastern Europe. The intrinsic complexity of remote clean up operations continues to drive research and development in all aspects of teleoperated and telerobotic systems. Challenges and accomplishments in this application area are discussed in the next section.

Hazardous Site Clean Up Applications

Robotic and remote systems have been used in assessing the status of sites contaminated with hazardous

materials. These surveys are essential in planning and executing subsequent clean up operations. Such systems have been used most extensively in nuclear waste sites around the world because remote techniques are more common in many nuclear operations. There has been some use of robotic survey systems in chemical and biological hazard situations as well.

Survey Systems. Numerous robotic survey systems have been developed and used. The basic idea is to integrate a sensor suite, appropriate for the contaminants of interest, with a suitable mobile platform that incorporates remote and/or autonomous driving functions and requisite navigation and control functions. The desired output of the survey process is a *precise* map of contaminant locations and concentrations. Such systems have been developed for both outside and inside operations.

It was common practice in many industries for a number of decades to bury hazardous wastes in earthen trenches in isolated burial sites [VIDEO 591](#), [VIDEO 592](#), [VIDEO 593](#). Usually, useful records of what materials were buried at what locations either did not exist or were not accurate. In fact, the general conditions of such buried waste sites are often unknown to the extent that human entrance is not allowed. As a result, the first step toward remediation is to quantitatively assess the physical and hazard conditions of the site. The mobile robot shown in Fig. 58.12 is an example of a survey system used to evaluate nuclear waste buried waste sites. The robot's location is monitored with Global Positioning System (GPS). The suite of sensors includes eddy-current probes and ground-penetrating radar that reveal density contours, radiation detectors, and gas emissions monitors. This system was an initial prototype that could be operated from a remote driving station or operated in autonomous programmed trajectory mode. The system was controlled using a radio communication link. Its unique feature is that it was designed with minimal use of ferromagnetic materials to minimize interference with the magnetic subsurface sensors.

The mobile characterization system shown in Fig. 58.13 is a similar concept for radiation survey of floored areas. This particular system uses a Cyberbot commercial mobile platform, triangulation of optical fiducial markers for localization, and operates primarily in a full autonomous mode. The objective in this application is to reduce labor costs and eliminate error-prone tedious human operations.

Excavation Systems. The actual remediation of buried wastes ultimately leads to digging and object-handling type operations. Various types of systems in-

Fig. 58.12 Prototype buried waste survey robot (courtesy of Los Alamos National Laboratory)

Fig. 58.13 Mobile characterization system (courtesy of Oak Ridge National Laboratory)

volving integrated mobility and manipulation-like functions have been developed. One of the most popular and low-cost approaches has been to retrofit conventional excavation equipment with sensor and actuators that allow remote and robotics operations. Such systems have been used in explosive ordnance disposal also. The system shown in Fig. 58.14 is called the teleoperated small emplacement excavator (TSEE) and is a prototype remotely operable backhoe for such applications. The unit included a multi-camera remote viewing system that is the primary basis for teleoperation. Radio and tether communications connections are used to allow the human operators to be displaced up to several kilometers from the hazardous operations.

Deactivation and Decommissioning Systems. In recent years, one of the most complex forms of hazardous operations is the deactivation and decommissioning (D&D) of defunct facilities where nuclear radiation or toxicity hazards preclude human presence.

Fig. 58.14 Remotely operated excavator (courtesy of Oak Ridge National Laboratory)

D&D can be thought of as remote demolition for the most part. Some operations are crude such as knocking down building structures and debris removal. Other operations may involve careful disassembly of equipment and devices, size reduction and packaging of handling/storage. These operations are essentially the inverse of remote maintenance and require the dexterous use of tools and handling of objects. Tools include saws, hydraulic shears, impact wrenches, and the like. Planning and situational awareness are very important in demolition-type operations because the physical layout and stability of the basic environment is changing during the process. Effective remote viewing (adjustable multiview capabilities) and acoustic sensing are essential. Audio feedback from the remote environment provides the human operator with the ability to monitor the normalcy of tooling operations such as sawing. D&D applications require manipulators that are both dexterous and massive. Experience has shown that payload capacities on the order of 100 kg are needed to deal with debris handling, typically with manipulators of the type shown in Fig. 58.15. Figure 58.16 is a frame view from one of the remote viewing cameras used to operate a similar system that was used to D&D an old experimental nuclear reactor. A manipulator is being used to teleoperate a conventional circular saw to segment a large-diameter aluminum tank. This operator view of the remote environment provides a realistic perception of the task environment lighting conditions and complexity.

In recent years, numerous remote manipulation systems for nuclear applications have been developed around industrial robots. These systems are augmented with sensors and master controller arrangements to facilitate teleoperation. This approach offers significant cost savings and the level of teleoperation performance achievable in complex task environments has steadily increased [58.50–54].

Applications in Large Scale Science Experiments

High radiation levels resulting from materials activation in the target areas of high-energy particle accelera-

Fig. 58.17 SNS Telerob EMSM-2B Dual arm servomanipulator

Fig. 58.18 SNS Telerob EMSM-2B master control station

tor experiments often require remote operations. Since these are unique scientific experiments, they involve complex and specialized equipment that results in some of the most challenging remote operations in the world. Nonetheless these highly specialized remote operations still involve the basic elements of remote operations summarized in Fig. 58.1. The most recent example of this class of remote systems is the comprehensive remote handling system developed as an integral part of the Spallation Neutron Source (SNS) located at the Oak Ridge National Laboratory [58.55].

The SNS is a neutron scattering facility in which uniquely high-flux neutron beams are generated by impinging high-energy protons on to a mercury target. The mercury is activated to the extent that the contact dose rate in the associated piping and vessels can be over 10^5 R/h and are long lived. The design and operation of this target system are such that it must be periodically replaced or refurbished. The mercury tar-

Fig. 58.19 SNS remote handling control room

Fig. 58.20 SNS pedestal manipulator system

get system and its support infrastructure are located in a shielded hot cell that includes a comprehensive remote handling system. The hot cell remote handling system is comprised of combinations of conventional mechanical master/slave manipulators, overhead cranes and a state of the art dual arm telerobot. Details of the overall system are provided in [58.55]. The focus of this discussion will be the telerobotic system.

Figures 58.17 and 58.18 show a dual arm force reflecting servomanipulator system, Telerob EMSM-2B, that is mobile in 3-D throughout the hot cell by virtue of a overhead bridge (X,Y motions) and rigid telescoping tube (Z motion). The manipulators are 6 dof and each have a 245 N continuous capacity and 445 N peak capacity. A 2200 N auxiliary hoist is integrated into the bridge trolley to facilitate handling heavy objects with the telerobot. The bridge system can be teleoperated or robotically pre-programmed. A second dual arm servomanipulator package (Fig. 58.20) is part of a mobile pedestal mounted system that is specifically designed in the high bay area over the target hot cell. The control room, Fig. 58.19 includes 21 flat panel displays

Fig. 58.21 Fukushima Daiichi Nuclear Plant after tsunami had inundated entire site to depth of over 13 m and subsequent hydrogen explosions. (courtesy of Japan Atomic Energy Agency)

that can be used with any of the 11 remote cameras located in the hot cell. The telerobot operator is located at the far end of the room and can operate either standing or sitting. This overall system is functionally similar in concept to advanced servomanipulator systems discussed in the earlier sections. The system has been in operation since 2006 and has been successfully used in several major mercury target diagnostic/refurbishment campaigns. The SNS remote system has shown that the electromechanical equivalent of traditional MSM's with full remote hot cell mobility is practical and reliable. Larger scale nuclear facilities involving higher level of radiation are certain to follow the remote handling philosophy represented by this system. Because this class of electrical servomanipulators have all of the real-time digital control features of modern robots, greater use of programmed and intelligent control concepts for certain types of remote tasks is expected in future.

58.2.3 Lessons Learned from the Fukushima Daiichi Disaster

Japan has not only been at the forefront in the development of robots to help in disaster situations, but has also, sadly, experienced a major recent disaster of the kind anticipated by robotics researchers and engineers for decades previously. This disaster provided a reality check for researchers and exposed just how far we still need to progress before robots can be relied upon to perform routinely in hazardous environments.

The March 2011 tsunami precipitated the Fukushima Daiichi nuclear reactor disaster (Figs. 58.21 and 58.22). Even though the reactors were shut down at the time, they still required significant cooling water supplies as they had been only recently shut down.

Fig. 58.22 Underwater reconnaissance robot being evaluated in search for human remains following the March tsunami, Japan. (courtesy of Prof. Shigeo Hirose)

The tsunami destroyed the diesel back-up generators required to keep the cooling water pumps operating. The resulting temperature rise in the reactors led to gas explosions that severely damaged the reactors, their cooling systems and the containment buildings, spreading radioactive contamination over a large area of nearby land and ocean.

As Kawatsuma and his colleagues explained, many different kinds of robots had been developed as a result of earlier research and development programs [58.56]. Unfortunately, at the time of the disaster most of these robots were either inoperative, unable to be repaired and made ready, or unsuitable because of the need for tether cables, or reliance on Wi-Fi communications which could not be operated satisfactorily in the contaminated nuclear environment (Chap. 60.4). Several teleoperated construction machines developed for

the 1991 Mt. Fugen volcanic disaster were successfully deployed to clear contaminated wreckage and debris [VIDEO 578]. Robots originally developed for reconnaissance work, primarily investigation of unexploded ordnance, were supplied by British and American sources [VIDEO 579], [VIDEO 580], [VIDEO 581]. However only limited operations could be completed with these robots as they could not reach many of the places where they were needed. In the first months following the disaster, only one robot, the Japanese designed Quince from Chiba Institute of Technology, was successfully deployed inside the reactor buildings for several weeks before it failed with a wiring fault. At the time of writing, it had not yet been recovered for repairs [VIDEO 582], [VIDEO 584]. Since then more robots have been successfully deployed to the site, though still with limited operational capabilities.

The disaster exposed the need for prior planning and continuous training, rehearsal and cooperation between research and development agencies, defence disaster relief agencies, robotic systems manufacturers and engineers at the hazardous facilities where the robots

would be used. Rather than individual robots, systems of which robots form a part need to be developed, including shielded vehicles to allow close-up monitoring and control by human operators [VIDEO 583]. Continuous updating of robot systems is needed: some robots that could have been deployed relied on obsolete electronic and computer components that could not be replaced. Following this disaster, we can expect a significantly increased effort to deploy robots over the coming years to deal with the consequences of similar events.

The Fukushima Daiichi disaster and other operations following the March 2011 tsunami demonstrated that, as in the other applications discussed above, robots can still only be expected to perform a niche role. Robots have only performed consistently in such environments after decades of development, and investment in developing trained operators with appropriate maintenance and support facilities. Our ability to realistically predict the capabilities of robotic operations in unforeseen hazardous environments is still very limited.

58.3 Enabling Technologies

There are a number of technology issues that are key to the design and implementation of mobile robots that can operate effectively in different types of hazardous environments. A few of them are touched upon here to give the reader additional insight into the foundational aspects of this class of robots.

58.3.1 Mobility Issues

Hazardous applications such as fire fighting, EOD, and demining require the ability to operate on uneven ground in indoor and outdoor environments where a normal wheel-type robot cannot easily operate. Most mobile mechanisms are classified into wheel type [58.57–60], track type [58.61–66], and leg type [58.67]. For negotiability in uneven ground, the wheel and track types need additional linkages with ground adaptation. There are two kinds of this adaptation: active and passive adaptation. Active adaptation uses an additional actuator to alter the linkage's motion while in passive ones the linkage motion is controlled by the ground conditions and gravity effects.

Stability Conditions

Stability should be considered in the design process to prevent rollover on uneven ground including stairways, steps, and natural terrain. Stability can be investigated

in terms of three parameters: *center of mass*, *supporting area*, and *stability margin*. Static stability requires that the center of mass remains inside the supporting area, as shown in Fig. 58.23. The supporting area is a polygon built by the edges connecting each contact point on the horizontal plane. A conventional vehicle has limitations in rugged terrain due to a fixed center of mass with respect to the body coordinates. The center of mass greatly affects the stability margin (the minimum length between the center of mass and edges of a supporting area). If the center of mass is located out

Fig. 58.23 Stability condition

Fig. 58.24 Wheel configurations

Fig. 58.25a,b Mobile robots with active adaptation mechanisms: (a) Packbot (after [58.68]), (b) Andros Mark V-A1 (after [58.64])

of the supporting area, rollover can occur. The stability margin of a conventional vehicle is mainly determined by the terrain inclination. Many vehicles are designed to have a low center of mass, thereby obtaining a large stability margin on a slope. Furthermore, a vehicle is often designed to have multiple bodies to overcome this limitation. For a multiple-link mechanism, the center of mass varies and the relative motion of links when traveling over the landform also alters the supporting area.

Active Adaptation Mechanisms

An active adaptation mechanism uses an additional actuator to generate motion of the adaptation linkage on rugged ground. Although additional actuators and

linkages are required, the adaptation mechanism can overcome variously shaped rugged landforms.

It is known that a vehicle can negotiate an obstacle which is smaller than the wheel radius. One may think that a vehicle which has large wheels can pass over rough terrain like a monster truck. However, most applications require a small vehicle to drive between obstacles.

A deformable wheel or its equivalent mechanism can be adopted: insufficiently inflated wheels, as shown in Fig. 58.24a, adapt to irregular terrain by deformation of wheels. However, their size should be big enough to negotiate rough terrain, so this concept still has size limitations. Their equivalent mechanisms are relatively compact and yet they need sophisticated articulation mechanisms, as shown in Fig. 58.24b. Two wheels are attached to a link that rotates about a main body. Therefore, revolution and rotation of wheels are made as shown in Fig. 58.24b. If rotation is provided by actuators at the main body (i.e., an active mechanism), the vehicle has an equivalent wheel whose radius is equal to that of the rotation. The vehicle in Fig. 58.24b can pass a step by carriage rotation, although the radius of a wheel is smaller than the height of the step.

Many track-type mechanisms have multiple linkage structures with active adaptation [58.63–66, 68]. When traveling over uneven ground, these mechanisms can negotiate rugged ground by changing the configuration of multiple track mechanisms, for example, typical multiple-tracked robots with active adaptation such as Andros [58.64] and Packbot [58.68], as shown in Fig. 58.25a and 58.25b, commonly use a small active additional track called a flipper. When moving on relatively even ground the robot can reduce undesired track resistance by lifting up the flippers. When climbing up stairs, touching the flippers down to the ground can increase the stability by enlarging the supporting area. Snake-like robots use active interconnecting joints [58.65] and have the potential for mobility and manipulation.

Passive Mechanisms

Passive adaptation mechanisms do not use any additional actuators; rather they simply utilize the gravity effect to generate adaptation to irregular ground. This approach is less adaptive but enables the operator to drive the robot easily because he (or she) does not have to take care of controlling the adaptation mechanism. Passive mechanisms usually include various kinds of passive linkages activated by irregular ground conditions.

For the wheeled vehicle shown in Fig. 58.24b, a passive mechanism can be designed in which no additional actuators are needed, for example, when a wheel

Fig. 58.26a,b Mobile platforms with passive adaptation: (a) Solero (after [58.60]) and (b) Robhaz-dt3

meets a sill whose height is greater than the radius of a wheel, it will become stuck. Then high torque is exerted at the wheel since the stall torque is usually greater than the normal rotation torque of the wheel. In this case, a closed linkage without any actuator except the driving wheels can generate a passive motion to climb over a step [58.58], for example, a smart mobile robot with passive adaptation called Solero (depicted in Fig. 58.26a) can climb up an obstacle by lowering the instant center of rotation of the passive four-bar linkage when coming into contact with the vertical surface of the obstacle [58.60].

Similarly, multiple bodies with tracked and chained passive joints can also adapt to irregular terrain. The track type is inherently insensitive to the unevenness of ground  **VIDEO 584**. Thus passively chained multiple-tracked bodies can provide greater reliability and better capabilities in ground adaptation. For example, a mobile robot with a passively chained double-tracked mechanism called Robhaz (shown in Fig. 58.26b) is a practical design with simply adapted multiple tracked bodies with passive joints [58.66]. As depicted in

Fig. 58.27a,b Passive adaptation of double-tracked mechanism: (a) positive deflection and (b) negative deflection

Fig. 58.26, two tracks of the Robhaz rotate positively or and negatively according to the contact situation between the track and the stair surface. Based on this behavior, in terms of the lower center of mass (Fig. 58.27a) and the supporting area (Fig. 58.27b) better stability in stair climbing than that of a single-tracked vehicle can be achieved.

58.3.2 Manipulator Design and Control for Hazardous Object Handling

Manipulation is essential for EOD missions. Generally, EOD missions have two phases: (1) approach, and (2) object manipulation to achieve ordnance neutralization. The second phase is generally controlled by teleoperation. Both the human's careful control and innate intelligence, plus appropriate manipulator design and control, are needed for such dangerous tasks.

Design Requirements

Unlike industrial manipulators, the design of manipulators for many robots in hazardous environments does not require very fast movement. Instead, high payload, light weight, and compactness are more important. Therefore, many manipulator designers locate actuators and reducers, which typically have high weight and large volume, on the base or lower links. This reduces the weight of the moving parts of the manipulator and offers better stability and dynamic control properties. Consequently, they have a thin profile, as shown in Fig. 58.28a,b. This characteristic is usually associated with explosive ordnance disposal-type robots that

Fig.58.28a,b Hazardous application robots with manipulator: (a) Packbot with manipulator and (b) Robhaz-dt2 with manipulator

require access to congested areas and normal human living spaces. Mobile robots used in other hazardous environments can be much larger, depending on the specific applications.

58.3.3 Control for Hazardous Tasks

In most cases, the operator does not have much information about the environment around the robot and the manipulator. He may have very limited vision, and unexpected collisions between the manipulator and obstacles can easily happen, even if he (or she) tries to be very careful. The robot should be able to handle these risks by appropriate design of the manipulator and good control algorithms. There are several ways to solve these problems.

Proximity sensors that detect nearby objects can be used to avoid a collision before it occurs [58.69]. However using many proximity sensors necessitates large wiring bundles and complex manipulator design. Force control is also a good way to handle collisions.

When a collision occurs, the manipulator can move away from the collision point by using force/torque sensor data. Often a six-axis force sensor attached at the end-effector of the manipulator is used for the force control [58.70]. Many researchers have developed stiffness/compliance/impedance control methods for a manipulator with a force sensor. However, this method can only handle a limited collision zone – only the end-effector or the manipulator *hand* – because the sensor cannot sense contact with intermediate links, while a collision could occur at any point on the manipulator. For this reason, some manipulators use joint torque sensors at all of their joints [58.71]. When using a joint torque sensor, contact at any point on the manipulator can be sensed, however, gravity compensation and errors in the transformation from the joints to the Cartesian space introduce further difficulties.

The stability of telerobotic systems, particularly when force feedback or reflection is involved, remains a critical issue. Systems involving significant data communication time delays are even more difficult. National Aeronautics and Space Administration (NASA) groups have studied stability and bandwidth issues numerous times over the years; one of the more recent studies is provided by Uebel et al. [58.72]. Energy methods have been applied to this problem showing promise for enhanced stability and performance [58.4, 73].

Master Controllers for Teleoperated Manipulation

In teleoperation, the robot is designed to be a faithful slave to deal with a dangerous task while the operator uses a control interface to direct the slave from a safe location. The user interface usually provides a means for:

- Sending position commands to the manipulator.
- Providing contact force feedback or force reflection to the user.

Ideally, the design goal of a user interface is to make it *transparent*, so the operator feels as if he or she is directly manipulating the object handled by the slave manipulator. To achieve this transparency, there are several design issues:

- Simplicity:
 - All indicators are unified as one scene.
 - All input button and joystick are integrated into one haptic device.
- Intuitiveness:
 - High-level command by speech recognition.
 - Human-friendly feedback such as graphical displays and human voice.

- Motion command matching between the haptic device and the slave in Cartesian space.
- Portability:
 - Small/lightweight and human-friendly design for wearability
 - Tetherless operation without communication lines and additional power.

An example of wearable multimodal user interface is provided by [58.74], as shown in Fig. 58.29. The operator wears a head-mounted display (HMD), head tracker, and headset to interact with the slave. A six-degree-of-freedom haptic master is attached on his waist together with the standalone controller, and the operator grips its handle to telemanipulate in Cartesian space. With wearable hardware, the user can walk around to gain a better view during teleoperation using wireless communication. It is composed of major three operator interfaces.

Speech and Auditory Interfaces

An operator usually sends two types of commands to the robot: selection and continuous motion commands. For example, the selection between mobile and manipulation mode, the reset of the robot arm and mobile base, the on/off and reset of pan-tilt motors, speed selection for the mobile platform, selection among installed cameras are defined in the selection commands. Voice commands offer convenience. When the operator says a word that has been predefined as a command, the speech interface can sense that word and, if the speech recognition system successfully recognizes it, the recognized command pops up on the HMD for confirmation. Finally, the operator decides whether to execute or cancel the command with a confirmation button on the haptic master.

The auditory interface synthesizes the human voice using a speech synthesis engine. It can warn of the approach of an obstacle by sound, or reveal the distance and direction to a laser-designated object nearby.

Wearable Haptic Interfaces

A wearable haptic device is shown in Fig. 58.29. The base linkage is designed as a serial RRP mechanism to measure a translation, and an RRR z - y - z rotation mechanism is attached at the end of the base linkage.

Figure 58.30 shows a wearable haptic master device for teleoperation of mobility and manipulation systems. It has six degrees of freedom for motion input and three degrees of freedom for force feedback.

To achieve a compact design and reduce its weight, a tendon-driven mechanism is designed into each joint. Due to weight constraints, only three actuators are installed for force feedback, and each actuator is specially

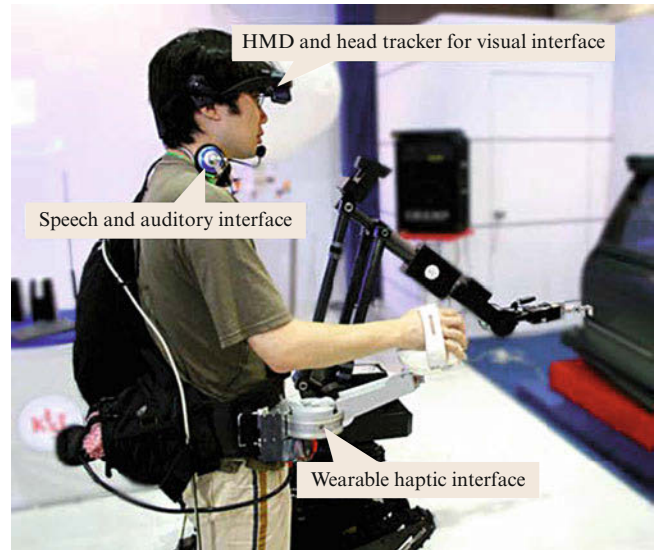

Fig. 58.29 Appearance of wearable multimodal user interface

Fig. 58.30 Picture of wearable haptic device

designed to fit the joint. Because a passive actuator is better than an active actuator with respect to power density (power per unit volume or weight), small magnetorheological (MR) brakes have been developed. They are installed at each joint of the base linkage for force feedback. Also a compact brake drive with current feedback capability has been designed, which reduces the response time of the MR brake. The controller is packed into a bag that is attached to the back side of the waist.

Visual Interfaces

The visual interface integrates the robot's view, the status of sensed data, and the status of speech commands. Since the slave includes a stereoscopic camera, the user sees a three-dimensional view on the head-mounted display (HMD). The operator wears a head tracker and it generates a pan/tilt command from the two-degree-of-

freedom head motion. In the integrated system, head tracker data is used to command the direction of the remote viewing camera, thus the user easily looks around the environment of the robot, as shown in Fig. 58.31.

Moreover, the head tracker is useful to indicate an object as a target. The operator moves his head and looks at a target to get information of direction and distance, then triggers a laser displacement sensor that is placed in parallel with the pan-tilt camera. A virtual reality overlay is prepared with the reported data, as shown Fig. 58.31. The recognized speech command is highlighted on the left for confirmation. These are overlaid on the remote video source pictures and unified into a single scene. Finally the operator sees the stereoscopic picture and the status of the robot at a glance on the immersive HMD. The overlaid view is shown in Fig. 58.31c.

58.3.4 Data Communications

Robots used in hazardous environments are almost always mobile so that they can move about an area of interest with flexibility. The combination of mobility and intrinsic operation across a physical or hazard barrier introduces unique problems with respect to bidirectional data communications (Fig. 58.1). Communications from the operator location to the robot is necessary to achieve remote control or teleoperation. Communi-

cations from the robot to the operator are essential for situational awareness. The transmission of the electrical and/or optical signals comprising such data communications can be quite complex due to a host of factors such as penetration of physical barriers, signal transport delays, signal attenuation, and data throughput requirements. Data throughput requirements are dominated by the feedback of visual imagery or remote camera views from the mobile system. Channel capacity necessary for audio feedback and control are small in comparison. If the mobile system involves precision manipulation with force feedback, bidirectional data channels on the order of 1 Mb/s are required.

For a mobile robot with high-fidelity manipulation, multichannel remote viewing, and other sensors, on the order of hundreds of Mb/s are required for the data communications path from the remote environment to the operator station while on the order of ten Mb/s are needed for the bidirectional control link. Data throughput requirements can be reduced through data compression hardware provided there is no significant increase in latency (time delay) which can degrade control by humans if the delay exceeds 100 ms. The choice of communication means is not easy: while wireless communication seems attractive, when multiple robot systems need to cooperate in a shared space, the communication systems need to be designed with this in mind. All too often, communication systems have evolved to support only a single robot system within a given operating region. Tethered cables provide high bandwidth, but pose extreme difficulties in unstructured environments, and when multiple robot systems need to work together (Table 58.1).

58.3.5 Energetics

Another key challenge in fielding mobile robots in hazardous environments is in the area of energetics including power supply, consumption, conversion, and management. The specifics of the given environment often restrict the types of power supply/conversion that are permissible, for example, the use of combustible fuels and internal combustion engines is seldom allowed within coal mines, refineries, gas plants, offshore platforms and nuclear facilities but can be entirely acceptable in demining and other outdoor operations. The most common power systems used for research robots are electrochemical batteries and electric motor drives. The power and energy density map [58.75] given in Fig. 58.32 shows the fundamental situation for mobile robots used in hazardous environments. For perspective, a small passenger automobile is estimated to need a minimum of 200 Wh/km to meet road demands, which in turn translates into 500 Wh/kg. This

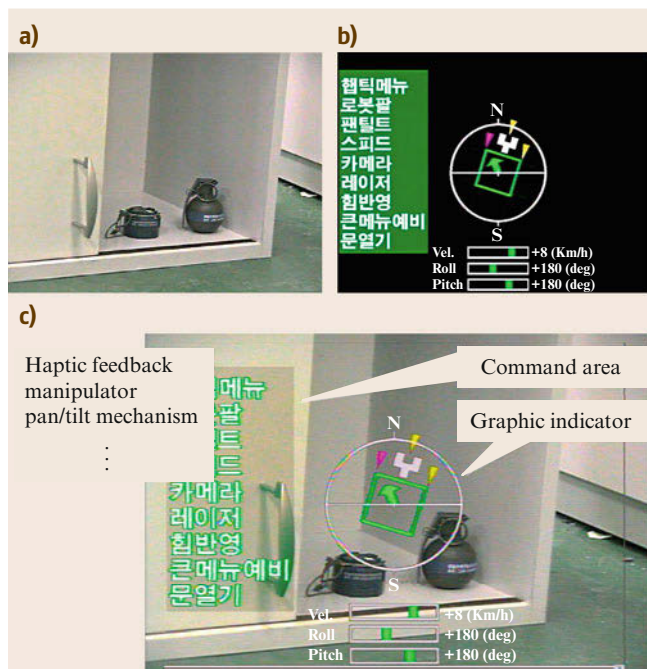

Fig. 58.31a–c Appearance of integrated visual interface: (a) camera view (b) overlay source view (c) user view

Table 58.1 Example data communications requirements (minimum)

Type	Single channel resolution	Typical standard system
Standard black-and-white remote television (typical for rad hard technology): 600 × 400 pixels 30 frames/s 12 bit gray scale	≈ 10 Mb/s per viewing channel	30–50 Mb/s for 3–5 channels
Color remote television: red, blue, and green = 3 × black and white	≈ 30 Mb/s per viewing channel	90–150 Mb/s for 3–5 channels
Color high definition (HD) 1080p television: 1920 × 1080 pixels 60 frames	~ 1.5 Gb/s per viewing channel with encoding compression ~ 3 Gb/s uncompressed	5.5–15 Gb/s for 3–5 channels
Control 12 bit resolution input and output 200 Hz sampling rate	≈ 4.8 kb/s per control channel	48 kb/s – ten control servo channels
Audio feedback 15 kHz signal capture 12 bit resolution	≈ 180 kb/s per audio channel	540 kb/s – three remote micro-phones

is why hybrid electric vehicles that combine spark ignition engines with battery-powered electric motors are becoming popular. A large mobile robot with dual manipulators operating in the payload range of hundreds of kg would have power requirements similar to these and would be well above the 100–200 Wh/kg range that batteries can provide. A force-reflecting six-degree-of-freedom robot manipulator with a 20 kg payload will have a peak power consumption on the order of 10 kW. If a particular application domain is amenable to the use of spark ignition engines, the order of magnitude of power density compared with any type of battery-powered system makes implementation feasible. If pure battery power is necessary, then considerable attention

must be given to the design, including state of charge monitoring and mission provisions for recharging. In the future, emerging fuel-cell technology may provide better solutions for mobile robot power systems.

58.3.6 System Architectures for Real-Time Mission Control

Because of the intrinsic nature of hazardous environments where uncertainty and lack of geometric structure are prevalent in the task environment, shared control architectures are commonly used. The degree of human interaction runs the gamut from pure teleoperation (manual control) to high-level intelligent control operations (autonomous). For example, most low-cost EOD type robots utilize simple manual control architectures, while at the other end of the spectrum, the Mars rovers operate as autonomous agents responding to mission-level commands from human operators on the earth. The basic architectures for real-time mission control are summarized in Fig. 58.33 [58.76]. Also, see *Sheridan* for a comprehensive discussion of architecture principles and design [58.44]. Between the manual and autonomous control exist combinations of computer assistance and semiautonomous (i.e., selective and in situ task automation) functions intended to improve remote work performance by either reducing operator workload or allocating tasks more suitable for computer control to autonomous execution. It is important to recognize that, as one moves from manual control toward autonomous control, the data throughput rates for communication and control are reduced because high-level commands are comparatively small packets of information while force-reflection manual control of a manipulator, for example, requires visual feedback and high-bandwidth control interconnection

**Fig. 58.32** Power and energy density for various power storage and supply systems

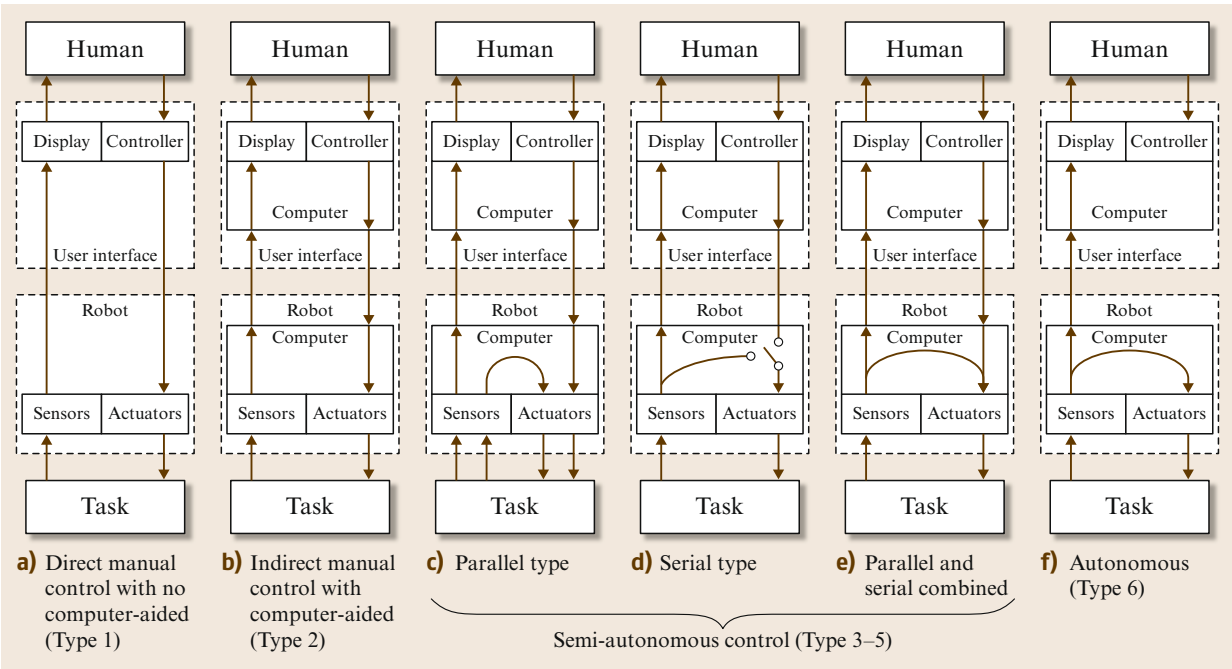

Fig. 58.33 System control architectures

of the slave and master controller. The data communication bandwidth available influences control architecture. Untethered undersea applications usually require semiautonomous architectures because of the bandwidth limitations of acoustic communications links.

As intelligent systems research advances, it is expected that, for hazardous situations, robots will em-

ploy semiautonomous and autonomous architectures to a greater degree as a fundamental approach to overall performance optimization. Operators will be able to choose the control mode based on the task needs and the likelihood that autonomous execution can be reliably achieved. In this human-centered way, task execution mode will be matched to best achievable performance.

58.4 Conclusions and Further Reading

If we are to learn anything from the experience of the last decade we must appreciate that robotics research is just one step in the development of tools that extend human capabilities. This search for improved tools is as old as humanity itself, so great patience is required [58.77].

Researchers need to make significant advances on four different fronts: mechatronics design, sensing, machine intelligence, and problem understanding:

- Mechatronics designers have to trade gains in precision, dexterity, mobility, and strength for losses in endurance and reliability. We are mostly well short of biological (e.g., human) capabilities except for high-precision applications. Machines have much the same environmental tolerance as people. Machines need special precautions against

- While electronic sensors can go far beyond biological capabilities, hazardous applications still present problems far beyond present capabilities as we have seen in the case of landmine applications. Radiation levels that are lethal for humans can also quickly kill electronic sensors. Extreme heat or cold limits sensor performance, as can contamination, and even insects.

- Advances in usable machine intelligence have been much more difficult than many expected. The only real progress has been achieved with capabilities often associated with clever people: logic, mathematical manipulation, and playing games. While recent advances have enabled a remarkable degree of understanding for some insect perception and motor capabilities, the social behaviour of insects still largely defies present-day understanding. However, teleoperation and supervisory control can make up for this deficit in the medium term. Shortcomings in machine intelligence represent less of a barrier than the other three fronts.
- Understanding the intended application and economic factors has proved to be equally important for researchers. Early success from exploiting specific opportunities can generate confidence that inspires others to persevere with more difficult general problems. Failures in understanding the desired task performance, particularly with respect to economic factors, can undermine confidence and the credibility of research efforts. Attempts to develop landmine clearance robots provides a useful case study that illustrates some of the difficulties in developing robots for hazardous applications.

There is no question that future teleoperators will become hybrid telerobotic systems that allow seamless transfer between manual and autonomous operations. Specific tasks will be selectively automated by operators for the purposes of enhancing quality and/or reducing subtask execution times. Early systems will continue to incorporate high levels of human interactivity to accommodate the limitations of current intelligent systems technology. Real-time execution of complex control algorithms and virtual-reality-like graphics engines (which are really useful) have become routine. Robust machine learning that allows human task execution skills to be captured through learning by observation or imitation is gradually becoming realizable. Advances in mass production of microelectrical mechanical systems (MEMS) technologies has greatly reduced the cost of sensing devices. In the next decade, telerobots for hazardous environments will become smarter and their relationship with their human operators will become more cooperative and less interactive. Human operators will supervise the operation of multiple telerobots: at the moment, the number of support people required for real operations is a multiple of the number of robots.

59. Robotics in Mining

Joshua A. Marshall, Adrian Bonchis, Eduardo Nebot, Steven Scheduling

This chapter presents an overview of the state of the art in mining robotics, from surface to underground applications, and beyond. Mining is the practice of extracting resources for utilitarian purposes. Today, the international business of mining is a heavily mechanized industry that exploits the use of large diesel and electric equipment. These machines must operate in harsh, dynamic, and uncertain environments such as, for example, in the high arctic, in extreme desert climates, and in deep underground tunnel networks where it can be very hot and humid. Applications of robotics in mining are broad and include robotic dozing, excavation, and haulage, robotic mapping and surveying, as well as robotic drilling and explosives handling. This chapter describes how many of these applications involve unique technical challenges for field roboticists. However, there are compelling reasons to advance the discipline of mining robotics, which include not only a desire on the part of miners to improve productivity, safety, and lower costs, but also out of a need to meet product demands by accessing orebodies situated in increasingly challenging conditions.

There was a time, in recent history, when improved productivity and lower mining costs could be achieved purely by the economies of scale that arise from the use of larger equipment [59.1]. However, this era is likely over. Today's mining companies and equipment manufacturers have been making renewed efforts in the

pursuit of new and innovative approaches to the business of resource exploration and mining.

Among these efforts has been a move toward increasingly autonomous mobile equipment and processes. For example, major suppliers of mining equipment for both underground and surface mining operations now offer

robotic driving, dumping, and other materials handling functionalities. What is more, some global mining companies are now operating their own technology-focused divisions, each with goals of bringing new technological developments to their mines worldwide.

Finally, there exist several emerging frontiers for mining, where robotics is already playing a critical role. These include not only very deep and high altitude mining, but also undersea mining and extra-terrestrial mining.

59.1 Modern Mining Practice

Mining is an ancient and broad practice, dating back to Palaeolithic times (43 000 years ago) [59.2] and involves the extraction of materials from the Earth's crust for utilitarian purposes. Today we mine minerals (e.g., gemstones, metals, salt, coal, and many others), aggregates, natural gas, and petroleum. These resources are used, for instance, to make the tools we use, shelter, food products, medicine, and clothing. Try to imagine, for a moment, a life where you endeavored to use (or build a robot from) absolutely nothing derived from mining. We benefit greatly from mining, but there is also increasing pressure and international recognition that the often negative environmental, safety, and social implications of mining and mineral processing must be curtailed and balanced with economic and lifestyle considerations. Robotics can play a vital role in all of these efforts.

In this section, we briefly provide some introductory background about the fundamental stages of mining, common to most operations, and discuss what drives the field of mining robotics, as well as its unique challenges, technical and otherwise.

59.1.1 Stages of Mining

Almost all mining operations have five fundamental stages [59.3]:

1. Prospecting
2. Exploration
3. Development
4. Exploitation
5. Reclamation.

Prospecting involves the initial search for valuable materials. This stage is normally carried out by geologists, and deposits may be located at or below the surface. Prospecting usually happens by either direct visual examination or by indirect methods (e.g., through the use of geophysical techniques) that look for anomalies in seismic, magnetic, electrical, electromagnetic, and/or radiometric variables of the Earth. Geochemistry and geobotany techniques are also employed. Although robotics has not yet played a pivotal

role in the search for minerals on the Earth, planetary geologists have been collaborating with roboticists for planetary prospecting; e.g., [59.4] and references therein.

In the *exploration* phase, the objective is to determine as accurately as possible the size (*tonnage*) and value (*grade*) of a deposit. This process is sometimes called *delineation* and more often than not involves collecting samples of material by drilling. Similar to prospecting, robotic exploration drills for mining are not yet common for surface exploration on the Earth. However, there has been a significant amount of work on robotic drilling in extreme environments, such as undersea and planetary exploration; see [59.5] for a good introduction and ample references.

The development and exploitation phases of mining are where tools and techniques from robotics have been, to date, applied most. *Development* is the work necessary to bring a mine into production, and usual entails planning, design, construction (e.g., overburden removal, shaft sinking, underground access) and the installation of mine services (e.g., power, water, ventilation, etc.).

It is during the *exploitation* phase that the resource is physically extracted, processed, and shipped to buyers. How exploitation occurs depends on the selected *mining methods*, which depend on many factors. These include the spatial characteristics of the deposit, geologic conditions, geotechnical conditions, economic considerations, technological considerations (e.g., the availability of advanced tools), and environmental considerations. Generally speaking, mining methods can be divided into two categories:

1. Surface mining methods;
2. Underground mining methods.

Surface-mining methods are used when the deposit lies near the surface, are usually very large scale operations and have high production rates. Underground methods are used when the deposit is deeply buried. Such methods have lower production rates and are usually more technically challenging and hazardous for mine workers.

Figure 59.1 shows examples of robotic vehicles used in surface and underground mining. These technologies, among others, are discussed further in Sects. 59.2 and 59.3.

Mining must strive to meet the economic and environmental needs of the present while at the same time ensuring (or enhancing) the ability of future generations to meet their own needs. Mine *reclamation* is the process of closing a mine, recontouring, revegetating, and restoring the land and water to an acceptable post-activity state. The objective is to minimize any adverse effects on the environment or threat to human health and safety. Some reclamation activities involve the construction and monitoring of *tailings* impoundments, where waste from mining and resource processing activities is placed.

Recently, tools from robotics have been used to conduct bathymetric surveys of tailings ponds, which are unique environments with very specific safety requirements. Figure 59.2 shows a robotic maritime research vessel performing a bathymetric survey of a mine tailings pond at a potash mining operation in eastern Canada. Performing robotic surveys has been shown to be safer and more cost-effective [59.6].

59.1.2 Technology Drivers in Mining

In order to better understand the potential for applications of robotics in mining, one must appreciate what drives the development of equipment technology in the mining industry. Mining is a dynamic process that must deal with the uncertainties of *outdoor* environments, and is usually conducted in as a series of interacting unit operations (e.g., drilling, blasting, loading, hauling, and processing). The harsh, extensive, and unstructured environments found in mining often preclude the application of existing techniques from other industries (e.g., from manufacturing robotics) [59.7, p. 806]. However, the recent growth of mobile and field robotics has resulted in several opportunities for robotics in mining. These opportunities stem mainly from a set of primary technology drivers:

- **Working Environment.** Mines are often developed in harsh and remote areas. For example, several companies operate mines and processing facilities at high altitudes. Also, as mines strive to operate at greater depths, extremely high ambient temperatures and humidity pose greater health risks [59.8]. Robotics may serve to minimize infrastructure needs and physically remove people from such hostile environments.
- **Labor Shortage.** Miners have reported difficulties finding the skilled labor needed to support their operations [59.9]. The newest generation of workers is technologically astute, but holds a different attitude toward physical labor than previous generations. Robotization may be what is needed to entice this new generation into mining.
- **Health and Safety.** With increasing mine depths, growing equipment sizes and speeds, and the tight-

Fig. 59.2 Robotic maritime research vessel conducting a bathymetric survey of a mine tailings pond with overlaid example bathymetry map (Photos: Clearpath Robotics, 2013)

Fig. 59.3 Experimental estimates of multifactor and labor productivity for the mining industry in Australia (1986–2011) showing decreasing productivity since 2001 (after [59.10])

ening of government regulations, it stands to reason that the deployment of almost any new technology that enhances the inherent safety of mining will be viewed positively at all levels.

- **Equipment Maintenance.** Maintenance costs and machine failures can make up a very significant portion of mine operating costs [59.11]. Moreover, operators often push equipment to its performance limits. Recent wisdom from the field of reliability engineering suggests that the automation (or

partial automation) of mobile equipment may help to significantly reduce downtime and maintenance costs [59.12].

- **Operational Efficiency.** There are a great number of areas in which efficiency improvements might be realized by the application robotics in mining. The most obvious lies in the fact that production time is lost during shift changes and breaks, resulting in much less than the desired 24/7 runtime. Not as obvious, and more difficult to quantify, is the less-than-optimal way in which underground mines typically operate. Without global and real-time control over the assignment (and movement) of machinery, the ability to optimize production performance through, for example, reduced dilution and increased recovery is also very difficult [59.1].
- **Sustainability.** Environmental and social responsibility are expected of modern mining companies and equipment suppliers. The alleviation of emissions (e.g., through the coordination and optimization of fleets) or reduction in power consumption by reduced operating demands (e.g., ventilation support) might be realized by way of real-time monitoring and automation of equipment.

Figure 59.3 shows multifactor and labor productivity for the mining industry in Australia between 1986 and 2011. Arguably encompassing all of the factors above, this data shows a worrisome decrease in productivity since the turn of the century, and some believe that robotics might help to reverse this trend [59.13].

59.2 Surface Mining

Surface mining is characterized by high tonnage operations, massive mobile equipment, and challenges that can include difficult environments (e.g., dust, fog, and extreme weather) together with remote locales and a strict need for keeping costs low.

59.2.1 Automated Haulage

Haulage is the process of moving material from one location to another. In the surface mining context, this is typically achieved using *haul trucks* (Fig. 59.1a), which move material from the point of blasting/excavation to the point of processing or stockpiling. The material being moved is either the desired economic quantity or overburden, and the destination is usually dependent on the load in the truck.

Haulage is a repetitive process, and the one to which automation can bring significant benefits, particularly

with respect to safety. Between 1989 and 1991, haul trucks were involved in 42% of the accidents and 60% of the fatalities in surface mining [59.14]. As with most mining equipment, there are also potential benefits of automation in the areas of productivity, repeatability, and reduced maintenance costs. Although it is too early in the history of robotic mining equipment to precisely define these benefits, the lessons from port automation (which use machines of similar scale, albeit in a more benign environment) have shown that maintenance costs of autonomous straddle carriers (in particular tyre wear and fuel costs) are reduced by approximately one-third [59.15] over their conventionally operated counterparts.

Autonomous Haul Trucks

Autonomous haul trucks can be thought of as mobile robots operating in a difficult, dynamic environment. As

such, they are required to have systems to address the standard issues of sensing and perception, situational awareness, localization, and control. The unique challenges presented in surface mining not present in other robotics applications include:

- Scale (haul trucks can carry up to 400 t of material).
- Mining pits often restrict the view of the sky, which can dramatically decrease global navigation satellite systems (GLS) reliability.
- Surface mining environments are constantly changing, which limits the ability to install fixed infrastructure.
- Mixed manually operated and automated fleets of machines, which places strict requirements on safety and integrity.
- All-weather operational requirements.

In the commercial sector, both Caterpillar and Komatsu had demonstrated the ability to automate haul trucks as early as the mid-1990s [59.16]. However, it was not until 2008 that the first commercial deployment of Komatsu driverless trucks was realized in the Gaby Mine, operated by Codelco in Chile [59.17]. This was followed closely by a deployment by Rio Tinto at their West Angelas mine in the Pilbara, Western Australia [59.18] ( VIDEO 145), where they have operated continuously since and have moved more than 50 million t of waste.

The Komatsu trucks operate using a high-precision global positioning system (GPS) as the primary localization sensor, radar sensors for obstacle detection and situational awareness, a proprietary wireless communications system, and are given tasks (load, haul, dump, etc.) using a proprietary scheduling system developed by Modular Mining Systems [59.18].

At the time of writing, similar systems by Caterpillar [59.19] and Hitachi [59.20] are also in various stages of trial and deployment, although there is scant information available publicly regarding the specifics of their designs and operation.

The automation of mining haul trucks is still an area of active research, however, primarily due to the challenging nature of the mining environment as previously noted. New positioning systems [59.21], situational awareness systems (Sect. 59.2.10), and planning and scheduling algorithms [59.22] are all under active development, and are intended to improve robustness, safety, and productivity, respectively. If each of these challenges can be addressed, robotic haulage technology will be able to be applied in a much greater range of operational scenarios than is currently possible.

59.2.2 Fleet Management

Fleet management is a catch-all term that may define a number of different technologies used in mining. Commonly though, fleet management is divided into three main tasks:

1. Position (and perhaps materials) monitoring
2. Production monitoring
3. Equipment task assignment.

Fleet management solutions are typically deployed to an office environment and allow operators to quickly survey large amounts of mine data so that appropriate actions can be taken in real-time on the mine-site. Computerized fleet management must integrate and evolve with the deployment of robotic mining machines.

Position Monitoring

The position of mobile equipment is commonly reported via wireless communications to a mine or region's database, where it can be queried by a visualization application. This provides a real-time picture of the movement of all equipment that has been enabled for such operation and allows an operator to quickly assess whether planned operations are proceeding as expected. Material movements may also be monitored in a similar fashion, but the material type (ore or waste) and grade must usually be entered manually by an operator. However some parameters, such as weight, are measured by the system.

Production Monitoring

Given that vast quantities of data may exist (particularly from robotic machines) that give a historical account of the evolution of a mine, or group of mines, this data can be used to provide detailed reports to mine management, and may also be useful as part of a continual productivity improvement process. Examples of production monitoring data may include machine cycle times, average maintenance cycles, machine failure events, payloads, or combinations of parameters (e.g., machine failure events vs. machine payload weight).

Equipment Task Assignment

At a typical mine, the equipment task assignment problem is addressed in a manner very similar to that of the urban taxi dispatch problem: A centralized authority decides, based on some predefined high-level goals, which machines must visit certain locations on the mine-site and perform some useful action. A machine

operator is generally given these instructions through a user interface located in the machine's cabin, which must be acknowledged and accepted prior to carrying out the task. The most typical implementation of the task assignment problem addresses the haulage scenario: when should a particular haul truck approach a given shovel, and when and where should it dump its subsequent load? Haulage is most commonly addressed, because it is here that even small changes in efficiency can have significant effects on overall profit.

Commercial Solutions

There are many commercial solutions for fleet management in the surface mining. The dominant solution is Modular Mining's DISPATCH system [59.23], which was developed in the 1970s. It implements an optimization algorithm to allocate trucks to shovels and dump sites, and contains modules for the other tasks of production and positioning monitoring. Modular Mining joined the Komatsu group of companies in 1996 and helped to deploy the FrontRunner autonomous haulage system described previously [59.24].

Other commercial systems include Caterpillar's MineStar software [59.25], Wenco's fleet management solution [59.26], Leica Geosystems Jigsaw suite of software and hardware [59.27], and Devex's Smart-Mine system [59.28]. These systems all now offer very similar overall functionality and differ mainly in implementation details.

Fleet Management Research

Although commercial systems for fleet management exist, there is still a substantial amount of research being undertaken, primarily in the area of task assignment optimization. Most commercial systems optimize task allocation using a heuristic that defines costs for allowing a shovel to become *idle* and/or allowing haul trucks to *wait* in a queue. In an ideal or optimal system, all items of equipment are fully utilized. However in practice, a higher cost is usually given to shovel idle time. The paper [59.29] gives a good overview of many of the commonly used heuristics used in task allocation optimization.

More recently, it has been acknowledged that heuristic, deterministic optimizers may not always produce truly optimal task assignments. This is primarily due to their inability to account for variability in the duty cycles of the items of equipment (i.e., they are stochastic rather than deterministic in nature), and any unforeseen discrete events, such as equipment failure, road blockage or operator error. The papers [59.22, 30–33] all describe recent approaches to overcoming these hurdles.

59.2.3 Robotic Digging

Mass excavation is one of the most important operations in mining. Being extremely sensitive to economies of scale and requiring a significant capital investment, it became a target application for robotic technologies starting in the mid-1990s. Surface mining typically uses large hydraulic excavators, hydraulic shovels, and electric rope shovels (Fig. 59.4). See also Sect. 59.3.3, which focuses on underground robotic loading.

Research in robotic digging involves systems design (including systems of systems), traditional robotics topics (sensing, planning, control), and tool-ground interaction problems. A framework for an intelligent earthwork system is suggested by [59.34], which discusses factors that can affect earthwork operation performance, identify key emerging technologies to support the implementation, the system architecture, and the system control strategy. A comprehensive review by [59.35] examined various aspects of sensing, planning, and control as they apply to earthmoving automation. Later developments in these topics are further discussed in [59.36]. Irrespective of the manned/unmanned aspect of the operation, a typical digging phase involves a number of critical steps: planning the bucket trajectory in contact with the ground, bank or muck pile; detecting when the bucket is full; and, detecting incipient stall and averting it. An analysis of autonomy requirements for each of these steps is detailed in [59.37] for the particular case of an electric rope shovel.

In other work, authors of [59.38, 39] proposed an autonomous excavation system for front-end-loader style machines that uses bucket force feedback, fuzzy logic, and neural networks for control. In their approach, a set of fundamental bucket action sequences,

Fig. 59.4 A rope shovel dumping into a haul truck (courtesy of Commonwealth Scientific and Industrial Research Organisation (CSIRO), 2006)

typically used by human operators, was compiled for use by the controller. A reactive approach, using fuzzy behaviours, was designed to act on force data to assess the excavation status and determine an appropriate control input. Experimental results, using a programmable universal machine for assembly (PUMA) 560 arm, were reported. Many more researchers have studied the robotic loading problem for homogeneous materials, such as soils and regolith. The majority of researchers have advocated the use of manipulator impedance or compliant motion control [59.40–43] and much of this work has focused on estimating the properties of the media [59.44] and on computing the resistive forces acting on the bucket during loading [59.45].

Invariably, all researchers agree that the biggest challenge to robotic excavation is the interaction between the tool and the terrain (ground, pile). This interaction is shaped by the properties of the media (e.g., density and hardness), the rock pile geometry, and the distribution of particle sizes and shapes. The problem is compounded by the fact that it is difficult to predetermine the exact nature of interactions prior to the execution of any particular excavation operation [59.46]. Significant effort was dedicated to modeling the interaction between the bucket and the terrain in excavation. This requires estimating the soil parameters online, since these parameters can vary significantly with the strata being excavated. The classical fundamental equation of earthmoving [59.47] used to determine the forces required for digging will fail to predict these forces if the soil parameters are not estimated correctly. Models for automated excavation using online estimation of soil parameters are discussed in [59.48].

Situational awareness, which includes both workspace and machine awareness, is another key aspect of robotic digging. Workspace awareness implies a knowledge of the terrain surrounding the digging machine. At a primary level, this knowledge is gathered using a sensor suite retrofitted to the machine, which in a typical configuration consists of a number of ranging sensors, an inertial measurement unit, and a GNSS unit. The acquired raw data is subsequently processed by higher level processes to detect the location and configuration of the dig and dump regions, and the location of other mobile equipment operating the workspace (e.g., haul trucks, utility vehicles). Laser rangefinders offer adequate resolution to segment the scene. An example of a workspace image in a form of a three-dimensional (3-D) point cloud acquired with a long range laser scanner installed on a shovel is shown in Figure 59.5. Color is assigned to the points based on intensity returns from the laser scanner.

Machine self-awareness is primarily concerned with determining the position and orientation of the bucket

with respect to a referential fixed with respect to the machine. It also includes all the usual status data for the main onboard systems: power plant, transmission, tool actuation, etc.. The position and orientation of the bucket are usually available from encoders and inclinometers. A better solution, however, is to use suitably placed ranging sensors that are able to track the bucket in all positions and orientations [59.49]. This latter method avoids the errors typically associated with backlash in joints and dynamic effects in inclinometers. The placement of the ranging sensors on the machine should consider the need to provide an image of the ground under the boom.

Autonomous digging systems offer the additional benefit of enabling dig-to-plan operation and reconciling actual versus planned volumes by providing accurate real-time survey information. In surface mining operations, the floor is usually mined and therefore disturbed before accurate surveys are executed, and the floor is graded on an as-needed basis to facilitate the movement of the mobile equipment operating in the pit [59.49].

59.2.4 Robotic Dozing

Dozers are used in most surface mines. Operating a dozer under conditions that are dynamic, with hazards that can vary and be subtle and difficult to recognize, adds to the complexity of the tasks that workers perform on these machines. Many of these tasks require oper-

Fig. 59.5 A top view of a 3-D point cloud coloured by intensity returns from a long range laser scanner installed on a mining shovel loading a haul truck (courtesy of CSIRO, 2008)

ators that are highly skilled in ground-engaging tool control and machine positioning. In addition, dozer operators are exposed to a variety of risk factors that may lead to health problems, including whole-body vibrations, awkward postural requirements, noise, and shift work. While machine guidance systems are now ubiquitous, they still require an operator in the cab and have known problems associated with their reliance on GNSS-based localization. As alternatives, some equipment manufacturers offer tele-remote-controlled and autonomous dozers, which eliminate the need for an on-board operator.

Remote control solutions for dozers have been in use for two decades. They cannot perform in poor visibility conditions (dust, fog, night operation, heavy rain) and do not offer the possibility of automating machine guidance and tool control tasks otherwise available if operating the dozer from the cab. Other problems include loss of situational awareness, inaccurate attitude judgement, and inaccurate depth perception. More recent commercial remote control offerings include force feedback. In the case of tele-operated control with negligible latencies, imparting force feedback to the operator has the benefit of allowing the operator to *feel* and control the machine.

In view of the limitations of remote control technologies, research on dozer automation has focused on semi-autonomous and autonomous system retrofits. Autonomous systems have already made significant inroads in the mining industry, and the acceptance for this technology is growing. Leica Geosystems offers an autonomous ripping solution for track and wheel dozers. Their system, called Leica J³ dozer autorip, provides a number of automatic functions, which include engine start/stop engine, automatic control for steering, throttle, transmission and ripper, accessories control, and an emergency fail-safe system [59.50]. The system also incorporates a path planner based on area coverage algorithms.

59.2.5 Autonomous Blasthole Drilling

Blasthole drilling is a mining process typically employed during the exploitation phase of surface mining. To excavate a material it must first be blasted to fracture the rock mass into small volumes suitable for haulage and processing. This is achieved by drilling a matrix of holes from the surface down into the rock mass; these holes are then loaded with explosives and blasted. The resultant fractured rock mass can be excavated by a variety of machines. The matrix of holes (or *drill pattern*) and the amount and type of explosives used are optimized to produce a desired rock size distribution in order to minimize the cost of processing; however, there

can be significant variation due to the variable nature of the underlying geology.

Blasthole drill rigs are usually large tracked vehicles with an articulated *mast* that contains the main drilling components: the drill motor, drill rods, and drill bit. To drill to depths longer than the mast, drill rods can be concatenated to form a long *drill string* as drilling is progressing. Like many home drills, most blasthole drill rigs are capable of rotary drilling, as well as hammer (or percussion) drilling. Rotary is typically preferred for softer materials, with hammer drilling primarily used for harder materials.

There are several facets of drilling amenable to automation: tramming (the process of moving the entire rig from one hole location to another), drilling, and the management of drill consumables (such as rod or bit changes). A *fully autonomous* drill rig should have all of these functions automated. The promise of automation is increased productivity and more consistency in the placement and angle of drill holes, which in turn should lead to better blasting outcomes. Consistency in post-blast fragmentation results in a significant economic impact.

There are several high-profile mining equipment manufacturers and companies that have developed fully automated drill rigs. Atlas Copco's Rig Control System (RCS) has reportedly made significant impact in increasing average tramming speeds (from 0.8 m/min to 2.6 m/min) and drilling efficiency (a savings of 1 h per 12 holes drilled) [59.51]. Flanders [59.51], and Rio Tinto [59.52] also have fully automated blast hole drill rigs in production.

59.2.6 Telerobotic Rock Breaking

Drilling and blasting results are often far from ideal and the resulting fragments of rock (called *shot muck* or just *muck*) can be larger than the projected size. Some of the shot muck can be too big for handling with a digging machine, and thus requires a secondary blasting. Other boulders can be handled by the digging and hauling machines but are still too large to fit in the mouth of a primary crusher. In this latter case, rockbreakers are used to achieve a further reduction in ore and rock size.

A rockbreaker consists of a large 4-DOF (degree of freedom) serial link manipulator arm that is fitted with a hydraulic hammer (Fig. 59.6), and is usually positioned in front of a run-of-mine (ROM) bin. The bin is fitted with horizontal bars at the bottom that prevent oversized rocks from entering the crusher below (this arrangement is called a *grizzly*). The size of the grill openings is made in such a manner that only rocks small enough to be crushed may pass through. Larger rocks do not fit and therefore must be broken. Haul trucks car-

Fig.59.6a,b Rock breaker at rest over the ROM bin (a) and breaking a rock on grizzly (b) (courtesy of CSIRO, 2007)

rying ore from a nearby quarry dump their load into the ROM bin. Typically, an operator uses a line-of-sight remote control to operate the arm.

Rio Tinto is pursuing a programme to automate the vast majority of its Pilbara iron ore operations in Western Australia, and control the operations from the Remote Operations Centre (ROC) in Perth, situated over 1000 km away from the Pilbara region. This effort includes the development of a telerobotic control system for the primary rockbreaker at the West Angelas mine in collaboration with the CSIRO [59.53]. This system addresses known drawbacks in teleoperation (limited communication bandwidth, high latency in the real-time video feedback, lack of spatial situational awareness, etc.) by improving the intelligence of the control system at the remote/machine end (e.g., Cartesian motion and collision avoidance capability) and by providing the operator with a mixed-reality interface that combines live video with 3-D computer visualization.

Each rockbreaker is fitted with a number of sensors to detect its pose in space, and actuated by signals that bypass the existing remote-control system. PTU (pan, tilt, zoom) cameras are fitted to poles on either side of the ROM bin and a pair of high-resolution digital

stereo video cameras were mounted below. At the remote end, in the control room, the operator is presented with an overview of the rockbreaker from a wide-angle video stream augmented by a synthetic computer image (Fig. 59.7). The operator is able to *walk around* the rockbreaker in the virtual world and inspect the rocks from different angles, enabling the operator to determine the appropriate breaking strategy. The operator deploys the arm using commands from a joystick, and as the arm is commanded to move, the motion of the arm is replicated in the 3-D scene. Simultaneously, both PTZ cameras follow the tip of the hammer. When the operator is ready to break the rock, he/she can switch his/her attention to the live video stream, which can be used to monitor the breaking of the rock. Once complete, the arm can be automatically sent to the rest position.

59.2.7 Automated Loading Unit and Truck Interactions

The main loading units used in surface mining are electric and hydraulic shovels and hydraulic excavators. Given the large volumes of material that need to be moved, and the comparatively small size of loading and hauling units, cycle times are closely monitored. In the continuous pursuit of efficiency, mining engineers dissect cycles to look for potential savings. One area of interest is truck spotting, which is the process of manoeuvring the haul truck into a position and orientation that is ideal for the loading unit to dump material into the truck's tray (Fig. 59.4).

The ideal truck placement for loading has both productivity and safety implications. When a mining shovel is used for loading, the haul truck must be positioned in such a manner that the swing motion of the shovel is minimized and that the shovel boom does not need to lower excessively to reach the tray. If the haul truck is not placed optimally, the loader needs to reposition itself to tip with a full load in the bucket, which results in lost time. Lowering the loader arm excessively and/or an uneven distribution of load in the haul truck

Fig. 59.7 A mixed reality user interface combines live video and 3-D stereo reconstruction of the rocks above the grizzly (courtesy of CSIRO, 2008)

tray may result in injuries to the operators and property damage.

In open-pit mining, the shovel operator usually guides the haul trucks to the desired location (spotting) by placing the bucket in the location that is optimal for the dumping phase, and waits for the truck to move into position. A key requirement for achieving automatic spotting is the availability of a robust localizer, that determines the relative pose between the shovel and the truck. Currently, most of the commercial guidance solutions are based on the use of GNSS and GNSS-aided inertial navigation systems on both the shovel and the truck. This results in an indirect determination of the relative pose between the shovel and the truck.

These systems, however, do not provide a robust solution. For the haul truck, the proximity to the shovel boom and crowd arm can lead to a degradation of the GNSS solution due to multipath, while the placement of the truck near highwalls leads to a partial obstruction of the sky, with a loss of satellite tracking and a significant geometric dilution of precision. The guidance system on the shovel can be impacted detrimentally by the proximity to highwalls. Imaging sensors (e.g., laser scanners) can be installed on both the shovel for a direct determination of the relative pose between the shovel and the truck [59.55]. However, this solution has potential pitfalls, that are related to the sensitivity of the imaging sensors to environmental conditions such as dust, rain, and variable illumination during the day (or during the 24 hour day/night cycle in cases where cameras are used).

Some researchers have looked at modalities that mitigate these pitfalls. One possible solution, suggested

in [59.54], is to divide the space around the shovel into three zones: the outer zone, the handover zone, and the work zone (Fig. 59.8).

The relative size of the zones depends on the truck and shovel geometries, and the chosen safe operating speed limits within each zone. As the truck crosses into the handover zone from the outer zone, the spotting system flags the truck as active and begins sending commands to it. In this zone, the relative pose between the shovel and truck is determined indirectly, based on the method discussed above. In the handover zone the truck is sufficiently far from the shovel and the highwall, and therefore the localization errors due to multipath and sky occlusion are minimized. Once the vehicle crosses into the work zone, the spotting system begins computing the relative pose using the imaging sensors on the shovel.

Since the sensors on the shovel are also able to see the bench and other obstacles in the work zone, the shovel is able to direct the truck around obstacles as they appear in the work zone, and park the trucks as close to the bench as practical. In other words, since the shovel is actively aware of its environment, it is able to deal with changes to the environment as they occur. The spotting system generates an approach path that will bring the truck in the optimum position for loading, where this optimum is determined in relation to the characteristics of the shovel and the configuration of the dig face. The path is also optimized with respect to the positioning time. Spotting times may be further minimized by double spotting, when the shovel loads on both sides, as depicted in Fig. 59.8.

The above discussion focused on shovel–truck interactions. Similar issues arise when hydraulic excavators are used for loading. Comprehensive research results in autonomous truck loading using hydraulic excavators are discussed in [59.56].

59.2.8 Dragline Automation

Mining *dragline* excavators are massive electrically powered machines used in open-pit coal mining to remove overburden and uncover coal. A dragline comprises a rotating platform that supports the house (consisting of the engine room and operator cabin), boom and a bucket rigging structure, as illustrated in Fig. 59.9. The house rotates on a base known as the tub which rests on the ground. The mechanism has three degrees of freedom:

1. Rotation with respect to the tub;
2. Hoist by a cable passing over sheaves at the tip of the boom;

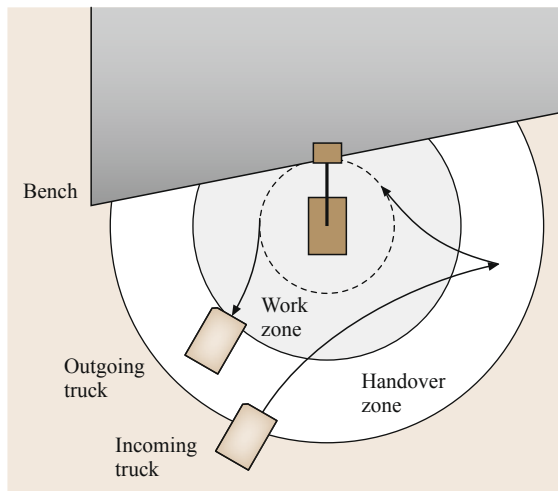

Fig. 59.8 Traffic management zones around a shovel in a double-spotting configuration, when the shovel loads on both sides (after [59.54])

Fig. 59.9a,b Schematic of a dragline excavator (a) front view (b) side view (after [59.2])

3. Drag by a cable passing over sheaves at the base of the boom.

Digging is controlled using only the drag and hoist ropes. When the bucket is filled it is hoisted clear of the ground and swung to the dump position by swinging the house and boom. The human operator fills the bucket by dragging it through the ground, lifts and swings it to the spoil pile, dumps it, and then returns to the dig point. Each cycle moves up to 100 t of overburden, and typically takes 60 s.

High capital costs are pushing the owners of these machines to continually look for avenues to maximize productivity (m^3/shift) in the presence of operator variability and maintenance costs (around 30% of operating cost) [59.2]. From this perspective, dragline operations seem ripe for deploying robotic technologies. However, the idea of completely removing the human operator from the dragline seat, while tempting from a research perspective, it is not widely entertained in the industry.

Swing control and digital terrain mapping are the two robotic technologies at the core of the dragline automation efforts. During dragline operation, the bucket naturally tends to swing with respect to the boom. A skilled operator can coordinate the boom slew motion so as to control the natural tendency of the bucket to swing during dumping and spotting operations. A novice operator typically requires six months training to become proficient. This warrants the development of a swing automation system to improve the productivity of the dig-to-dump and dump-to-dig phases of

a dragline operation. Automatic swing controllers offer the additional benefit of minimizing stress fatigue on the boom.

An implementation of a dragline swing controller is discussed in [59.57]. The control system moves the bucket between operator-specified dig, and dump points, passing through intermediate (via) points. The rather rigid programming of control (dig, via, and dump) points has a number of disadvantages. Firstly, as the spoil pile grows the dump point must be raised. If the automation system does not contain a model of spoil growth, the operator has to make adjustments by retraining the system, resulting in time losses. Secondly, if the operator does not correctly identify a via point at a critical area, such as the top of the high wall, the swing automation system will not know the high-wall is there and may attempt to swing the bucket through it. Augmenting the automation system with a digital terrain mapping capability provides a common solution to these problems.

One implementation of a digital terrain mapping solution for draglines is described in [59.58]. Maps were created using data from a real-time kinematic (RTK) GNSS system and a two-dimensional (2-D) laser scanner. The laser scanner was mounted at boom tip in such a way that the scanning plane intersected the ground underneath the boom, and tilted by about 7° with respect to the vertical. Tilting the laser minimizes the likelihood of the bucket and ropes blocking the laser's view. The terrain is scanned as the dragline swings during the normal operation cycle, a typical map is shown in Fig. 59.10.

Fig. 59.10 Image of a digital terrain map created from a long range laser scanner installed at the tip of a boom dragline (courtesy of [CSIRO](#), 2005)

The implementation of a digital terrain mapping function in dragline automation systems also enables the measurement of dragline productivity in real time. Commercial dragline monitoring systems can only measure the approximate weight of each bucket, and the approximate disengage and dump points. They cannot provide indications of where the where the spoil is located in relation to the dragline, of the actual volume of overburden moved, or how much re-handle took place [59.58].

59.2.9 Machine Positioning and Terrain Mapping

The task of establishing and maintaining the vehicle positioning (i.e., position and orientation) relative to an external frame of reference is a fundamental problem in autonomous vehicle navigation and control, and this hold true for mining applications. High-accuracy positioning technology is a dynamic area of research and development, spurred on by the advances in satellite positioning as well as by the current challenges for the technology in mining systems, especially in surface mining operations. The following initiatives are underway to improve the availability and robustness of current technologies, which have and will further enable the application of robotics in surface mining:

- Public GNSS systems (e.g., [GPS](#) and [GLS](#) (global navigation satellite system))
- Augmented public GNSS systems (e.g., [GPS](#) with [WAAS](#) (wide area augmentation system))
- Locally augmented GNSS systems (e.g., [DGPS](#) (differential global positioning system) or [RTK GPS](#))

- Pseudolite augmented GNSS systems (i.e., through the installation of Earth-based transceivers)
- Closed systems (i.e., wholly proprietary systems relying on a constellation of locally installed Earth-based pseudolites).

For example, in the mining domain, Leica Geosystems offers the Jigsaw Positioning System ([JPS](#)), a product that offers a significant breakthrough in addressing the major shortcomings of GNSS [59.59]. Based on a technology developed by the Locata Corporation [59.60], [JPS](#) is a ground-based network for positioning that in principle mirrors the functionality of GNSS. It circumvents the fallacies of GNSS by using a terrestrial network of transmitters that can be placed in optimal locations with respect to the mobiles being tracked.

Different from pseudolites, an example of technology for positioning in GNSS-denied environments is [CSIRO](#)'s wireless ad-hoc system for positioning ([WASP](#)) wireless tracking technology. The system can be configured as a mesh network and offers a unique combination of high accuracy, high resistance to multipath interference, low-cost hardware, and ability to be rapidly deployed [59.61]. The accuracy of [WASP](#) depends upon the radio propagation environment, and is typically better than 0.25 m under line-of-sight conditions, even in the presence of substantial multipath interference. The maximum range over which [WASP](#) nodes can measure range and communicate is typically over 400 m, and can exceed 1 km. As [WASP](#) can form a mesh network, the overall network size is not limited. The maximum location update rate is 200 Hz; however, there is a tradeoff between the number of nodes and update rate, and a typical update rate is 1–10 Hz.

Terrain Mapping and Surveying

The penetration of robotic and autonomous systems in mining, coupled with new computer aided tools for mine modeling and reconciliation, requires more accurate and timely information about the current state of the mine, and at higher spatial and temporal resolutions. In the traditional surveying framework, one obvious solution is to increase the number of surveys (reduce the time gap between successive surveys) and the density of survey points, while reducing the costs per survey. To address this, a number of vehicle-based scanning systems have been recently introduced to the market. The mode of operation ranges from stop-and-go-type systems (such as the Maptek I-Site), to continuous scanning mobile systems, such as those offered by Riegl (VMX 250), Topcon (IP-S2), and Trimble (MX-8). In general, these systems integrate high-end [LIDAR](#) (light detection and ranging) with GNSS-aided [INS](#) (inertial

Fig. 59.11 A 3-D map of a surface mine created from a mobile mapping system installed on a four wheel drive (4WD) vehicle (courtesy of CSIRO, 2012)

navigation system) and carry a significant price tag, which can limit deployment to a single dedicated survey vehicle.

On the other hand, consider the application of simultaneous localization and mapping (SLAM) in mining. SLAM is a mature area in mobile robotics and efforts are underway to transfer the technology to mining. Data-fusion techniques used in SLAM make it possible to use lower cost mapping sensors, which in turn enables mining companies to deploy the equipment on a multitude of utility vehicles and/or heavy-duty mining equipment (Fig. 59.11). As a result, the vast majority of survey work can be performed during the normal operation of the equipment in pits, on haul roads, or other site areas, without directly exposing surveying personnel to the perils of conducting survey work in high-risk areas.

59.2.10 Mine Safety

The increase in demand for resources has posed new challenges to increase productivity, while at the same

Fig. 59.12 Complexity of mining equipment interactions affected by adverse environmental conditions (courtesy of CSIRO, 2012)

time continually improving the standard of safety. Robotics is beginning to play a role in this. There are inherent risks associated with manually operating vehicles in mining environments. Operators work long shifts and the view from the driver's cabin can be very restricted. Furthermore, vehicle interactions are inherently difficult due to the size of machines, and can be further complicated by environmental conditions such as dust, fog, and snow (Fig. 59.12).

Each year there are hundreds of mine haulage accidents that result in significant numbers of injuries, even deaths, and large financial costs due to machine downtime and repair of equipment. According to the United States Mine Safety and Health Administration (MSHA) [59.62], from 2002 to 2008 the United States coal industry alone averaged 1206 accidents per year involving mobile equipment.

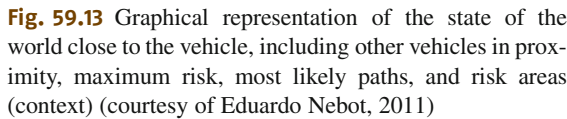

During the past few years, a number of approaches have been introduced to assist operators in becoming more aware of safety risks in the local environment. These technologies and methods include proximity awareness technology (PAT), proximity detection technology (PDT) and collision avoidance technology (CAT). It is important to note that, in surface mining, these existing technologies do not perform any control action. They merely provide information to the driver, who remains in total control of the vehicle.

Detection of Threats

In general, most safety incidents are from vehicle interactions with other vehicles, fixed infrastructure, or personnel. A large proportion of these incidents happen at low speed. This is most likely to occur on vehicle startup, or at the loading areas with interactions between trucks, shovels, loaders, and other ancillary equipment. These accidents are usually of low impact but can cause serious damage to equipment and significant loss of production.

The fundamental approach to reducing the likelihood of low-speed incidents is to provide the operator of large vehicles with aids to see into blind areas such as side or back of the vehicle. These aids are normally based on standard video or infrared cameras. The next level of risk reduction is achieved by incorporating automatic detection of resources and people in close proximity by utilizing range and bearing sensors. Radar is a preferred sensor modality for bad environmental conditions. Wide beam radars are very common but they are prone to false alarm. New recent developments mitigate this problem by using electronic-mechanical scanning narrow beam radar technology [59.63, 64].

High-speed incidents occur less frequently than at low speed, but often result in serious injuries and fatal-

ities. The time available to stop the vehicle or perform an evasive maneuver is reduced and consequently long-range detection of threats is necessary in order to take early preventive action.

Positioning, Context, and Road Maps

Positioning is one of the fundamental components of a comprehensive safety system. The incorporation of

The especially hazardous and generally unpleasant nature of underground mining environments, operator safety and fatigue, labor costs, and the repetitive nature of the ubiquitous load-haul-dump cycle all motivate autonomous and semi-autonomous and teleoperation-based solutions for underground machines and processes.

In mining, *remote control* typically refers to the control of a machine where the operator has a direct line-of-sight view of the machine. Remote control is normally used only for excavation (or *mucking*), not for driving

Determining the risk of a situation is entirely dependent on the context of the situation. One important situation context is the location, or more specifically the type of area the vehicle is currently operating. The expected behavior and driver intent [59,65,66] varies depending on whether they are driving on a road, parking in a designated area, or dumping ore in a crusher. Map information is required to allow the system to vary the information provided to the operator depending on the location. An example is shown in Fig. 59.13, where the map allows the operator to become aware of the risks, and complexity of the situation, independent of the weather or geometry of the terrain.

The ultimate goal of any safety system is to find a complete solution to the safety problem by introducing new technology, methods, and algorithms. It is very unlikely that this can be achieved with a single technology alone, perhaps with the exception of a fully autonomous system implementation. An active area of research and development aims to use both reactive and proactive approaches to solve the safety problem. At the reactive level, technology is used to assist the operator in recognizing and avoiding the safety risks. At the proactive level, managers are provided with tools to monitor, analyze, design, and improve the safety of the mining operation. This new comprehensive approach to safety has the potential to eliminate all accidents in the mine by integrating technology, procedures and intelligent algorithms to make the mine safer and more productive.

manufacturers are now finding benefit in the application of telerobotics, particularly to underground equipment such as LHD machines (Fig. 59.1b) and drills [59.67–69]. This is normally done by the real-time transmission of video and control signals to and from a remote control room; Figure 59.14, which shows a commercial teleoperation station.

However, teleoperated equipment may not be as productive as manually operated equipment, for example, due to visibility and issues related to reduced operator feedback. Recently, some researchers have proposed the development of semi-autonomous teleoperation systems, whereby the operator's actions are filtered by a machine control system that regulates operator commands with some degree of partial or *local autonomy* [59.70].

59.3.2 Autonomous Tramming

Autonomous *tramming* refers to automating the driving task of underground mining vehicles, which is often a repetitive activity. Most robotic tramming systems have been developed for LHD machines, such as the one shown in Fig. 59.1b, although some suppliers also have systems available for their underground haul trucks.

Several challenges exist that make the autonomous tramming problem difficult. For example, the large inertia of these vehicles and their hydraulically actuated, center-articulated steering mechanisms make them difficult to control at high speeds. Another is the problem of precise and real-time underground localization in the absence of global infrastructure (most notably, GNSS available on the surface).

Underground Navigation

Early autonomous tramming systems worked by outfitting the mine with signal-emitting cables [59.71],

Fig. 59.14 Teleoperator's station for control of underground robotic vehicles at the Kemi mine, Finland (courtesy of Atlas Copco, 2009)

reflective strips [59.72], light-emitting ropes [59.73], or reflective tape [59.74, 75]. Other systems required beacons, placed at strategic locations throughout the mine, which allowed the vehicle to estimate its position by measuring angles to the beacons and comparing the measured angles to those expected from a map of known beacon locations [59.76].

One drawback to these early systems is the time-consuming task of installing, localizing, and maintaining the necessary infrastructure, particularly as the mine advances. To the best of our knowledge, none of these systems ever saw widespread use in industry. The state of the art in underground autonomous vehicle systems is infrastructureless.

One of the first infrastructureless technologies was one initially developed by an Inco Ltd. spin off. The patent [59.77] describes the use of a map consisting of a set of interlinking nodes intended to represent the topology of the underground passageway environment. The nodes themselves are located at points of interest, such as at intersections, dead ends, etc. Thus, a topological map was used for navigation, which relied on an algorithm capable of classifying all of the possible tunnel geometries encountered in the mine. Steering the vehicle was then done by a lower-level reactive algorithm, which tried to keep the machine near the tunnel center. A range-sensing device was used to sense the distance to walls.

This topological and reactive approach to underground navigation and control was tried again after [59.77]; see also [59.78–81]. Recently, these methods have also been combined with radio frequency identification (RFID) tags to provide a global reference [59.82]. This general approach is what formed the basis for one of the first truly commercial autonomous LHD systems, which is now offered as a product by Caterpillar Inc. (see the following). However, the main drawback to this technology is that it relies on classifying tunnel and intersection topology. As roboticists know, misclassifications can happen in practice.

Inspired by advances in mobile robotics research, some considered the application of alternative map-based localization algorithms – the idea being to match sensor measurements to a map rather than by classifying tunnel topology [59.83, 84]. In most cases, a planar poly-line representation of the mine was used to help the vehicle navigate. This is the approach taken by Sandvik AB in their commercial offering. More recently, Atlas Copco Rock Drills AB entered the underground automation game by applying an approach similar in philosophy, which generates sequences of occupancy grid maps and subsequently uses these to estimate the vehicle's position in real time by way of an

unscented Kalman filter (UKF)-based algorithm [59.85, 86].

Vehicle Control

A machine control system capable of performing at or better than a human operator is necessary in order for robotic tramming systems to compete in industry with manual operation. Many researchers have proposed articulated vehicle steering controllers based solely on vehicle kinematics [59.87–90], while few have considered dynamics [59.91]. Others have contended that wheel slip is significant and should be explicitly accounted for [59.92]. The paper [59.86] describes a control architecture and implementation that permits high-speed tramming by handling hydraulic vehicle steering and driveline dynamics by explicitly forcing a bandwidth separation between low-level machine/actuator dynamics and the path-tracking control problem, which is solved at the kinematic level.

Commercial Products

Although product descriptions are not the primary focus of this chapter, it is worth briefly mentioning that there are (at the time of writing) three main commercially available underground vehicle automation products: Caterpillar MineStar system for underground [59.93], Sandvik AutoMine [59.94], and the Atlas Copco ST14 ARV [59.85] ([VIDEO 142](#)).

Mobile equipment vendors, not third-party suppliers, sell all three. All three systems are infrastructure free. They all operate by scanning the vehicle's local environment with a 2-D SICK laser rangefinder and combining this data with wheel encoder information. All three systems operate in conjunction with a high-

speed wireless network. What is more also all perform autonomous dumping. A schematic of the Atlas Copco product is shown in Fig. 59.15, highlighting the sensor and control components used for robotic tramming.

59.3.3 Robotic Loading

Despite a significant amount of research effort in the field of robotic excavation, none has yet resulted in the widespread development or adoption of autonomous or semi-autonomous excavation technologies in the mining industry. Although this section focuses on loading from an underground mining perspective, robotic loading is also applicable to surface mining operations (Sect. 59.2.3).

Robotic excavation is especially challenging because of the dynamic and unpredictable nature of the bucket-rock interactions. Also, a dig controller must manage not only the motion of the excavation arms (e.g., boom and bucket links), but also the penetration rate as determined by the motion of the mobile platform. As a result, performance is highly influenced by the conditions of interaction between the machine and its environment. For example, the forces that act on a bucket as it is actuated to penetrate a rock pile may vary significantly depending upon the properties of the media (e.g., density and hardness), the rock pile geometry, and the distribution of particle sizes and shapes [59.95, p. 562].

It is important to distinguish between excavation in homogeneous materials, such as soil, sand, or regolith, and the challenge of excavating fragmented rock as in mining, which usually has a significant distribution of particle sizes. Fragmented rock may consist of both *finer* (i.e., very small particle

Fig. 59.15 Scooptram (or LHD) components for robotic tramming, including SICK scanning laser rangefinders (front and rear), articulation angle encoder, drive shaft encoder, onboard cameras, and computing subsystems (courtesy of Atlas Copco, 2009)

cles), *oversize* (i.e., particles too large for the excavation tool), and a range of sizes in between. Figure 59.16 shows an EJC 9T LHD machine conducting robotic digging experiments in fragmented rock.

The robotic loading problem can be split into two fundamental tasks [59.96]:

1. Dig planning
2. Dig execution and control.

Dig planning constitutes the problem of deciding where and what to dig, possibly considering the geometry of the rock pile, the distribution of particles, and the physical characteristics of the loader and bucket. Dig control refers to algorithms for modifying plans based on the nature of the media encountered, so as to efficiently fill the loader's bucket. This task of the problem is particularly challenging in fragmented rock.

Dig Planning

Machine vision has been proposed as an enabling technology for dig planning. The paper [59.97] describes a laboratory-scale excavation system that utilized camera data for control and navigation. In [59.98], a scale-model system was built to mimic the motions of an LHD and different loading strategies were developed that depend on sensed information about the rock pile. Similar work, described in [59.99], employed a vision system to obtain images of the rock pile. In their approach, these images were used to plan the excavation task based on an estimated contour of the rock pile. In more recent work, the authors of [59.100] conducted an experimental study of two novel approaches for selecting an attack pose from 3-D data, with the objective of eventually using this for the robotic loading of sand.

Dig Execution and Control

The dig execution and control tasks have been tackled by several robotics researchers during the past two decades. Much of this work has targeted surface mining applications (Sect 59.2.3), although some concepts are transferrable to underground. Targeting underground, in [59.101] it was suggested that the trajectory of an excavator's bucket through the rock pile should not have priority in a devised control scheme, since the objective is to effectively fill the bucket, not to follow a predetermined path. This was explored further in [59.46, 95], which proposed an algorithm for robotic digging that would respond to bucket-rock interaction forces sensed as changing pressures the excavators bucket cylinder by commanding a change in the cylinders retraction velocity, rather than its position. This strategy was based

on full-scale experiments with an LHD. Together with Atlas Copco AB, researchers at Queen's University in Kingston, Canada have recently demonstrated this admittance-based robotic loading strategy by way of full-scale experiments on a modified Kubota loader (on surface) and an ST14 LHD (underground), as shown in VIDEO 718.

59.3.4 Longwall Automation

Longwall mining is one of the main extraction methods for underground coal mining. This method is highly efficient in cases where thick seam reserves are present, with high-quality coal at shallow depth and benign geological conditions [59.102]. In the longwall process, a *shearer* – a machine with large rotating cutting drums – is driven back and forth across the seam, with each pass taking a massive slice of coal.

Figure 59.17 shows a schematic representation of a longwall mining equipment installation. Two long, horizontal and permanent tunnels known as *gate roads* are cut into a coal seam to form the main boundaries for a large rectangular block of coal, known as a longwall panel. The shearer travels in this panel along the face on a structure also housing an armored (or articulated) face conveyor (AFC) that carries the coal to one end of the face. The coal is then removed via other conveying systems to the surface. The roof is supported over this operation by a number of adjacent powered roof supports (also known as *shields* or *chocks*) which are each connected to the AFC. After the shearer passes, the chocks release from the roof, advance under hydraulic power into the cavity created by the removal of the coal, reposition the AFC, and re-support the roof [59.2].

Fig. 59.17 Schematic of a longwall mining equipment installation (courtesy of CSIRO, 2008)

A concerted effort to deliver automation solutions for longwall mining saw the establishment of the Longwall Automation Steering Committee (LASC) in 2000, comprising Australian Coal Association Research Program (ACARP) industry representatives, equipment manufacturers, research providers and mine safety authorities. With funding from ACARP, CSIRO and the Cooperative Research Centre for Mining Technology and Equipment (CMTE), now CRC Mining, embarked in a major project to deliver automation solutions for coal cutting and loading, maintaining face geometry and manipulating roof supports without human intervention.

Three issues were identified as critical for longwall automation [59.103]: Face alignment, horizon control, and creep control. Until recently, efforts to develop automatic controllers for face alignment were hindered by the lack of an automatic and reliable method for measuring the actual geometric profile of the longwall face. The solution provided in this project employed a high-end inertial navigation system to provide accurate shearer position and attitude information in real time. The system is shearer-mounted and is referred to as the Shearer Position Measurement System (SPMS). One of the major outcomes of this project was the development of open specifications for the SPMS, and as a direct result, all the major longwall equipment manufacturers now offer automatic face alignment systems.

The second significant technological challenge tackled by LASC was achieving enhanced horizon control (EHC). While face alignment occurs in the horizontal plane, horizon control occurs in the vertical plane, and is significantly more difficult. In order to maximize the extraction of coal and minimize the extraction of waste, the roof and floor cutting horizons need to stay within the coal seam. The EHC incorporates two independent horizon controllers: one for the floor and one for the roof. The set points for the two controllers are generated by an integrated cut model, which sits at the core of the EHC. The cut model incorporates real-time information from navigation sensors, coal interface detectors, seam tracking sensors, as well as off-line geological and geotechnical information.

Finally, *creep control* refers to maintaining the lateral position of the longwall equipment in the panel. As the longwall mining system progresses, the assembly of supports should not creep toward either of the two gate roads. The LASC solution measures creep using laser range finders that scan in a horizontal plane in the panel and roadway directions. The creep information is provided to the longwall shearer automation processing system and generates corrections in the face

profile in the form of a lead to either of the gate ends [59.103].

59.3.5 Robotic Explosives Loading

Many tasks in mining and construction require the driving of horizontal and inclined tunnels (or *drifts*) by drilling and blasting for rock fragmentation. Currently, drilling and blasting also remains the primary method for recovering ore from blocks (or *stopes*) in underground hard-rock mining. Blasting engineers design a blast hole pattern that specifies the size and location of the holes in order to achieve the desired rock fragmentation and minimize the damage to the rock mass left behind.

Blast hole charging is a two-step operation. In the first step, the operator places a primer assembly at the end of a flexible hose, inserts the hose into the blast hole, and pushes the hose until the primer reaches the end of the hole. A *primer* is a compact device containing high strength, sensitive explosives used to safely initiate the main column in the blast hole at a controlled time provided by the detonator. Initiation requires electric energy, usually delivered by detonating cords. The hole pushing is mechanized. In step two, an explosive emulsion is pumped into the hole through a hose, the hose is retracted as the explosive gradually fills the hole, leaving the trailing detonator wire. Once a ring of blast holes is filled, the detonator wires are joined and the rock is blasted.

A robotic explosive charging system (RECS) developed by the CSIRO [59.104] incorporates technologies that make the operation of loading holes safer with comparable or better productivity than otherwise possible. The system incorporates mixed teleoperation and robotic capabilities that allow the operator to load the entire pattern from the comfort and safety of the cab of the loading truck. The prototype RECS was developed for a mechanical manipulator derived from a Palfinger truck crane. The system is able to locate blast holes using the laser rangefinder attached to the arm end effector. An automatic arm pose control function is used to achieve a sweeping motion of the arm, during which the laser rangefinder collects images of the tunnel. These images are subsequently processed to extract blast hole locations, and presented to the operator via a human-machine interface.

Once the holes are identified in the scan, they are matched with the holes present in the blast plan and the operator is ready to proceed with the charging. The robot arm is sequenced to pick up the primer assembly from a magazine, and transfers it to the hole. The primer ends up at a pre-set offset from the

hole collar. In teleoperation mode the operator uses in-cab joysticks to insert the primer and the hose in the hole. The video system provides the operator with real-time video images of the relative positioning between the tip of the end effector and the blast hole collar.

In the work of [59.104], hole identification was carried out for 89 and 102 mm blast holes. While the hole diameter is used as a parameter in the identification algorithm, determining the hole length was not a requirement (this is not to say that in-situ validation of drilled versus planned is not important). During scanning, the robotic arm moves the end effector back and forth through the tunnel. The end effector is sequentially rotated, such that the laser is capable of scanning a full 360° pattern in the tunnel. Successful hole detection is influenced by the relative alignment between the laser beam and the hole axis. The larger the misalignment, the greater the chance of generating a false negative. Figure 59.18 shows a typical 3-D profile used for hole identification.

Visual servoing requires locating the tool in relation to the target hole. Cameras mounted on the end effector provide estimates of the location of blast holes with respect to the end effector. The control methodology does not require extensive knowledge of the manipulator physical parameters, and uses a minimal set of tuning parameters, to allow operators to make adjustments if and when required. However, finding an adequate solution raises a number of significant challenges when using a typical truck crane as a robotic arm.

59.3.6 Underground Mapping, Surveying, and Positioning

Mapping, surveying, and real-time equipment positioning are core services in many industries, and mining is no exception. In surface mining, the advent of the satellite-based **GPS** in the 1980s led to fundamental changes in the way everyday operations are carried out [59.105], with new applications being developed even more recently (Sect. 59.2). Based on GNSS, accurate site surveys, information systems, and robotic tools that enhance safety, improve productivity, and cost-saving maintenance operations, for example, have become commonplace in surface mining [59.1, 106].

However, similar progress has been made more slowly in underground mining because no directly comparable positioning technology currently exists for the accurate and real-time localization of mobile equipment in underground mining operations. This section discusses some tools and techniques from the field of robotics that have found their way into mining for such purposes as surveying, mapping, and equipment localization.

Underground Mapping and Surveying

At present, manually generated survey maps in mining are used for the design and construction of structures, ventilation, power, drainage, haulage planning, and tracking of development and ore extraction progress [59.107]. However, traditional surveying techniques are slow and laborious, involving many manual steps, infrastructure installation (e.g., retroreflective markers), and repeated measurements to obtain the necessary accuracy for the given application. Conventional survey maps are invariably a coarse approximation of the actual mine structure because, while individual observations may be accurate, few measurements are taken (i.e., poor resolution). Also, surveying is a regulated practice; thus the use of new techniques from robotics requires that current standards be updated.

Several recent advances out of the robotic mapping community show promise for applications in underground mining, and we mention just a select few here as examples. Authors from Carnegie Mellon University (CMU) [59.108, 109] describe robotic systems developed for acquiring volumetric maps of underground mine workings; specifically abandoned mines where ground conditions may be hazardous. **SLAM** results, based on data from 2-D scanning laser rangefinders, were reported from data obtained in two mines: a research mine in Bruceton, PA, and an abandoned coal mine in Burgettstown, PA.

Fig. 59.19 3-D SLAM-generated map of a decline at the Northparkes mine (after [59.112]); the gaps on the floor and ceiling are due to the blindspot between two vertically oriented SICK laser rangefinders; electrical cables can be seen along the left side wall (courtesy of So Jung Yun, 2012)

Some have developed techniques for robotic exploration and topological mapping [59.110] by focusing on the detection and matching of underground mine tunnel intersections as a basis for the creation of topological maps.

New scan registration techniques, such as 3-D-NDT (three-dimensional normal distributions transform) [59.111], have also been conceived specifically for underground mine mapping. Authors from the AASS in Sweden compared their results with the popular iterative closest point (ICP) algorithm on actual mine data.

Recently, researchers at CSIRO [59.112] demonstrated a 3-D SLAM solution, consisting of a spinning 2-D scanning laser rangefinder and industrial-grade micro-electromechanical system (MEMS) inertial measurement unit (IMU). The system was mounted on a site vehicle at the Northparkes mine (Parkes, NSW) that continuously acquired data at typical mine driving speeds. The deployed system mapped over 17 km of mine tunnels in under two hours, resulting in a dense and accurate geo-referenced 3-D surface model. Figure 59.19 shows an example of the generated surface model.

Underground Positioning and Tracking

The satellite-based GPS uses radio frequency signals that cannot usefully penetrate significant obstacles (e.g., rock); see any reference on the fundamentals of GPS [59.113, 114]. Although high-sensitivity receivers are being developed [59.114], these will almost certainly not function underground. For buildings, some have proposed the use of signal repeaters [59.115], but this is again not practical for most underground mine environments. These challenges necessitate a different approach for underground mines.

As a result, several alternatives for underground mining have appeared in recent years, many of which have limited functionality or are, as of yet, unproven. A recent summary, found in [59.116], presents a survey of the most commonly cited approaches:

- Employing RFID tags for event-based tracking of equipment and personnel [59.117].
- Use of radio signals (e.g., installed Wi-Fi access points) for signal strength-based positioning [59.118, 119], which is very difficult in underground mines due to severe multipath and shadowing, as well as non-line-of-sight propagation and the need for too many devices in order to obtain GPS-like accuracies.
- Dead reckoning using inertial sensors (e.g., IMUs) and odometry for only short-term machine tracking.
- Rock-penetrating very low frequency electromagnetic signals, generally limited to near surface (< 200 m) [59.120] with questionable accuracy [59.121].

However, none of these options yet offer a solution comparable to that provided by GNSS on surface. Another issue is that mining practitioners often do not appreciate the technical limitations of these approaches [59.116, 122]. As a result, some have recently proposed the adaptation of map-based localization techniques for underground mining equipment. For example, [59.123] describes a method for large-scale mapping that employs a combination of RFID tags (as landmarks) and occupancy grid mapping specifically designed to facilitate real-time underground vehicle localization.

59.4 Challenges and Industry Acceptance

Despite the latest uptake of robotics technologies in mining, significant challenges remain. Next, we briefly review the most significant ones that are likely to affect the diffusion rate of autonomous systems in mining.

59.4.1 Technological Challenges

One expression that describes the current situation of robotics in mining is *islands of automation*. This re-

flects the significant integration issues that exist in relation to fully autonomous and mixed autonomous-manual/remote equipment. The root cause of the problem is a lack of standards to which the various equipment manufacturers should align. Although steps are now being taken to develop these standards (Sect. 59.5.3), the situation is likely to persist for a number of years. In addition to the time it will take to develop the required standards, there will be a significant lag at the equipment manufacturers' end, associated with the rolling out of new products that align with these new standards.

Other challenges to the implementation of robotics technology in mining include:

- Reliability, availability, and fail-safe operation with graceful failure
- Ability to sustain productivity at current or better levels
- Mining in extreme environments and difficulties in developing the required supporting infrastructure
- Current design methodologies for mines and mining systems are not geared to support robotic systems
- Deploying systems in the field and the fact that every mine is different
- Provision of technical support, shortfall in skilled labor, lack of adequate training
- Poorly designed or challenging man-machine interfaces.

59.5 Challenges, Outlook, and Conclusion

This section briefly summarizes some of the primary challenges for robotics in mining, as well as examines some emerging themes within the field of mining robotics, beginning with those on the Earth and followed by a short discussion about planetary exploration and extra-terrestrial mining, all of which will rely heavily on robotic tools. The section ends with a short conclusion about the future outlook for mining robotics.

59.5.1 Technical Challenges

Despite the recent uptake of robotics technologies in mining, significant challenges remain. One expression that could be used to describe the current status of robotics in mining is *islands of automation*. This reflects the significant integration issues that exist in relation to fully autonomous, as well as mixed autonomous/manual/remote robotic equipment. One specific challenge, for example, is the lack of standards to which the various equipment manufacturers and technology developers should align. Although,

59.4.2 Socioeconomic Challenges

The resource industry has a conservative history, and the implementation of new technology and processes must overcome significant inertia. In general, the attitude of people, from those at the working face to senior managers and company executives, mirrors the attitude of the workforce in the manufacturing industry in the early days of industrial robotics; i.e., skepticism about technology and fear of losing one's job. The generational change is likely to alleviate the fear of technology, but robots will be regarded by many in the workforce as a *competitor* for years to come.

Some researchers in human factors also point to the over-reliance on the technology by operators as a possible outcome of spreading robotic systems in the industry. As a common trend across several domains, it was noted that automation and new technologies can sometimes result in operators engaging in more risky behaviours in automated systems [59.124].

Legal issues and insurance are two other factors that could create significant headwinds to the rapid proliferation of autonomous systems in mining or in other civilian activity for that matter. Actuarial analysis is very hard to do for a green field, such as commercial autonomous operations.

steps are now being taken to develop these standards (Sect. 59.5.3), it may take some time before equipment manufacturers roll out commercial products that adhere to these standards.

Some other key challenges for mining robotics include:

- Reliability, availability, and fail-safe operation with graceful and safe failure modes for very large equipment and (often) electric or hydraulically actuated equipment.
- Ability to sustain productivity at current or better levels when compared with current methods and systems.
- Mining in extreme and unstructured environments (e.g., far north, very deep underground, in harsh weather) and the difficulties in developing and supporting the necessary infrastructure in these environments.
- Current mining methods and design methodologies need to evolve so as to inherently incorporate robotic systems.

- Field robotics deployment challenges and the fact that every mine is different.
- Provision of technical support in remote areas, shortages of skilled labor, and the need to re-train existing personnel.
- Developing effective man–machine interfaces.
- Safely managing the colocation of robotic machines and human workers.

59.5.2 Socio-Economic Challenges

For the most part, the resource industry has a conservative history and the implementation of new technologies and processes must often overcome significant resistance to change. In many cases, the attitudes of people – from those at the working face to senior managers and company executives – mirror the attitudes of the workforce in the manufacturing industry in the early days of industrial robotics; i.e., skepticism about technology and fear of losing one's job. However, generational changes are likely to alleviate these challenges.

Some researchers in human factors engineering also point to the risk of over-reliance on technology by operators as a possible negative outcome of the proliferation of robotic systems. As a common trend across several domains, it was noted that automation and new technologies can sometimes result in operators engaging in more risky behaviours [59.124], which would not be looked favorably upon in mining.

59.5.3 Emerging Frontiers

There are several emerging frontiers for mining robotics, from the creation of standards to robots that improve safety in mining, and future-looking robots for mining asteroids and other extra-terrestrial bodies.

Emerging Standards for Mining Robotics and Automation

Due to the increasing prevalence of automation in mining, there is an immediate need to formulate standards for robotic equipment such that data may be exchanged freely among systems developed by different manufacturers. Currently, a tension exists between manufacturers, for whom it may seem the commercial imperative to design *closed* vertically integrated systems, and the mine operators, who would like any system they purchase to interoperate with all existing items of equipment.

There currently exists a data interchange standard known as the International Rock Excavation Data Exchange Standard (IREDES) [59.125]. This standard

uses the extensible markup language (XML) to define a three-level architecture:

1. Administration level that defines reusable data objects such as coordinate systems
2. Application profile level that covers general information for one application purpose
3. Equipment profile level that has detailed equipment specific information.

The IREDES standard currently covers drill rigs and LHD machines, with many prospective application profiles under active development.

There is also an ISO (International Organization for Standardization) standard called *Earth-moving machinery – Autonomous machine safety* (ISO 17757) [59.126] currently under active development. However, at the time of writing, there is no public information regarding this standard apart from its December 2012 approval. The standard will likely cover the risks inherent in large equipment automation, and common ways that those risks can be mitigated through design and/or procedure.

It is still early days for the standardization of autonomous mining machines, and current efforts are far from complete. However, it is a worthy goal, and one which will only increase in importance as more mining equipment is automated.

Mine Rescue Robots

Mining is inherently risky. Although infrequent today, many fatalities have occurred in mining and the necessity of a mine rescue strategy at every operation – particularly in underground mining – is clear. So why not use robots to assist with mine rescue?

Although not mainstream, mine rescue robots have been under development at a few research institutions, including at Sandia National Laboratories where researchers have focused on coal mines under funding from the United States National Institute for Occupational Safety and Health (NIOSH) [59.127]. In coal mining, the risk of explosions is high and poisonous gases may be present, particularly after a disaster. Their tracked Gemini Scout mine rescue robot is approximately 1.2 m long, equipped with an infrared camera (to see through smoke and dust) and gas sensors that allow rescuers to assess the situation before attempting a rescue.

More about mine rescue robots can be found in [59.128], including reference to the first known mine rescue robot prototype at the CSIRO, called Numbat [59.129].

Robotic Undersea Mining

There is a vast body of robotics research related to undersea applications and remotely operated underwater

vehicles (ROVs) (Chap. 51 of this book is dedicated to this topic). However, much of this work does not yet directly target undersea mining. Nevertheless, advances in robotics – specifically computer-based mapping, multivehicle coordination, as well as telerobotic drilling and excavation – are likely to make ocean floor mining a reality in the very near future.

Although the pursuit of marine mining dates back to the 1870s, large-scale operations have not yet been realized at least in part due to technological barriers [59.130]. Today, several venture mining companies, including most notably Vancouver-based Nautilus Minerals Inc. (TSE:NUS), are targeting polymetallic seafloor massive sulphide deposits. However, these resources are only accessible by using ROVs equipped with telerobotic seafloor production tools to disaggregate and collect the rock from the seafloor [59.131]. Thus, robotics is poised to play a significant role in undersea mining.

Planetary Exploration and Mining

Perhaps the next great frontier for mining is that of planetary exploration and resource extraction, whether for in-situ resource utilization (e.g., toward development of the Moon) or for return to the Earth (e.g., mining of asteroids for valuable materials).

Several enabling technologies that support autonomous off-world robotic excavation for large-scale habitat construction and resource extraction have already been developed. For example, researchers from the National Aeronautics and Space Administration (NASA) and CSIRO demonstrated remote excavation of a trench as an example of site preparation and regolith mining [59.132]. This remote excavation system consisted of a 1/7-th scale dragline excavator located at a CSIRO test facility in Australia, a control interface located at a NASA facility in the United States, and a communication network between the two. The tested use case scenario involved remote initiation of terrain mapping, and a click-to-dig user interface that allowed the specification of material transfer in terms of dig and dump points on the acquired terrain map. The terrain map was used to generate a collision-free

terrain-skimming path from dig to dump. The onboard path planner generated a bucket trajectory that included engaging the dig face (bank), filling the bucket and disengaging the bank. Tool force sensing was used as an input to the planner in order to constrain the dig speed and dig trajectory to remain within the operational limits of the machine and ensure adequate material flow into the bucket. The system successfully completed 50 consecutive cycles without any operator intervention. The average cycle time was approximately 63 s with the entire mission taking 52 min to complete.

There is also a thriving space exploration community, particularly within the mobile robotics community, and there is a complete chapter of this book dedicated to space robotics, Chap. 55. However, it is worth mentioning here that mining and planetary resource extraction have much in common and there is increasing cooperation between planetary geologists, mining equipment suppliers, and roboticists in problems related to Lunar and Mars exploration (e.g., see [59.4, 5, 133] and references therein for examples). Moreover, new commercial ventures, such as the widely publicized Planetary Resources, Inc., have been established with the aim of pursuing commercial extra-terrestrial resource discovery and utilization.

59.5.4 Conclusion

The desire to improve productivity, safety, and lower the costs of mining is a key motivator for the use of robotics in the mining industry. As highlighted in this chapter, several robotics-related advances have been made in recent history, for both surface and underground mining environments and, after a long courting period with robotics and automation, many mining companies are embracing robotics as a credible and practical tool. Moreover, with the emergence of *field robotics* as an increasingly popular subfield within the robotics research community, as well as the recent formation of networks, centers, and institutes that focus specifically on field robotics (some on mining), the domain of mining robotics appears poised to undergo accelerated growth on the Earth, undersea, and beyond.

60. Disaster Robotics

Robin R. Murphy, Satoshi Tadokoro, Alexander Kleiner

Rescue robots have been used in at least 28 disasters in six countries since the first deployment to the 9/11 World Trade Center collapse. All types of robots have been used (land, sea, and aerial) and for all phases of a disaster (prevention, response, and recovery). This chapter will cover the basic characteristics of disasters and their impact on robotic design, and describe the robots actually used in disasters to date, with a special focus on Fukushima Daiichi, which is providing a rich proving ground for robotics. The chapter covers promising robot designs (e.g., snakes, legged locomotion) and concepts (e.g., robot teams or swarms, sensor networks), as well as progress and open issues in autonomy. The methods of evaluation in benchmarks for rescue robotics are discussed and the chapter concludes with a discussion of the fundamental problems and open issues facing rescue robotics, and their evolution from an interesting idea to widespread adoption.

Robots serve as extensions of emergency professionals. During the immediate response to a disaster, robots can provide real-time data about the event and perhaps even directly aid in inserting mitigation devices

and sensors, turning valves, and moving equipment. As the immediate life-saving and stabilization phase of the disaster ends, robots can help with the economic recovery. Robots for disaster are an emerging technology,

and have not yet been widely adopted by the international emergency response community. However, as of 2012, they have been used in 28 disasters in Cyprus, Haiti, Italy, Japan, New Zealand, and the United States primarily for mining disasters and structural collapses or infrastructure damage. Robots have been used for hazardous materials accidents, often referred to as chemical, biological, nuclear, radiological, or explosive (CBRNE) events, most recently the Fukushima Daiichi nuclear accident. Both structural and CBRNE events are generally handled by urban search and rescue teams unless an industry-specific team assumes command. As a result of the breadth of the term *urban search and rescue* contributes to a misperception that disaster robotics is limited to urban or constructed environments. For example, although technically an urban event, wilderness search and rescue is often conducted by a local urban search and rescue team. In general, disaster robotics connotes extraordinary situations requiring special operations; fire fighting is not considered as part of disaster robotics as it is a *routine emergency*.

Disaster robotics can contribute to broad area activities, local incidents, and routine emergencies,

though this chapter will focus on the use of robots for disaster events. Interest in robotics for surveying wildland fires and flooding is emerging, and the few documented uses of robots are reported in this chapter. Robots are also being increased use in local incidents which do not qualify as true disasters. For example, several fire rescue departments in Japan and the United Kingdom routinely use small underwater robots for water-based search and recovery of drowned victims and the interest in the use of aerial vehicles for wilderness search and rescue is growing.

Disaster robots have not been widely adopted, but their use is increasing as the technology matures. The general lack of adoption is to be expected since the technology is new and the concept of operations for these novel technologies take time to evolve. Rescue applications are often similar enough to military operations that the same platforms can be adapted; however, some tasks are significantly different than their military counterpart, some are unique to rescue, and the human–robot interaction for civilian response diverges from military patterns of use.

60.1 Overview

Disaster response is always a race against time, to move as fast as possible to reach all potential survivors and yet move slowly enough to avoid creating additional collapses, damage, risk to rescuers and victims, or contention over airspace. The primary motivation is to save lives; robots can assist in meeting this goal either by interacting directly with victims or structures or automating support activities.

60.1.1 Motivation

Disasters are defined as a discrete meteorological, geological, or manmade event, that exceeds local resources to respond and contain. Disasters are distinct from an ongoing condition such as global warming. In practice, a disaster means that an agency has to engage additional specially trained experts and equipment. For example, a chemical spill may be routine and handled with existing personnel trained in hazardous materials or it may be horrific, such as the 1984 Bhopal disaster that killed thousands of people.

Disaster activities are often referred to by phases, though there is no single accepted model in emergency management. After an event, public officials are responsible for the life-saving *response* and economic *recovery* activities focused on maximizing benefit to the

largest population. Nongovernmental agencies may join with other officials and citizens in humanitarian *relief* efforts which are generally focused on benefiting individuals. Emergency professionals are also tasked with *prevention* of disasters and *preparation* should there be sufficient warning.

Disaster response activities are typically executed by the urban search and rescue (USAR) task force within a fire rescue agency who work with law enforcement, transportation officials, and others. USAR is often used synonymously with any response activity. The term *urban* can be misleading as it sounds like it is restricted to building collapses. USAR includes hazardous material response, as these materials most certainly have something to do with built structures. USAR includes *wilderness search and rescue* which often involves searching tunnels and abandoned mines, avalanches, not just locating lost hikers. It also includes *water-based search and rescue* which deals with saving victims of floods or high currents (also known as *swift water rescue*) or in the aftermath of traffic accidents where victims are trapped in cars that have plunged into a river or bay. Water-based search and rescue does not necessarily have urban structures but there is a similarity of rescue techniques and re-use of equipment.

Historically, disaster robotics concentrated on the response phase of a disaster. The disaster robotics community began to form in 1995 as the outcome of the tragic loss of life in the Hanshin–Awajii earthquake in Kobe, Japan, and the bombing of the Murrah Federal Building in Oklahoma City, United States [60.1, 2]. In both cases, it was easy to imagine how small ground robots may have been able to enter rubble to find trapped victims. As a result, research efforts began in individual laboratories. Two mobile robot competitions (the AAAI (Association for the Advancement of Artificial Intelligence) mobile robot competition in the United States, and the RoboCup rescue league internationally) were started in the late 1990s to engage the scientific community in rescue research. The first use of robots for response was at the 2001 World Trade Center (WTC) disaster, where ground robots were used to penetrate the deeply packed rubble. Since then robots have been used for response to earthquakes, hurricanes, mine collapses, bridge collapses, explosions, and flooding.

The deployment of disaster robots during the response phase offers many potential benefits. The 2010 World Disasters report [60.3] suggests just how many lives have been, and will be, impacted by urban disasters. Over 1.1 million people were reported killed from 2000 to 2009, with the total amount of disaster-related damage estimated at 986.7 billion US dollars. Of the victims in urban disasters, only a small fraction may actually survive. Consider from [60.4, 5] that the majority of survivors (80%) of urban disasters are surface victims, that is, the people lying on the surface of the rubble or readily visible. However, only 20% of survivors of urban disasters come from the interior of the rubble, yet the interior is often where the majority of victims are located, providing motivation for robots that can explore deep within collapses. The mortality rate increases and peaks after 48 h, meaning that survivors who are not extricated in the first 48 h after the event are unlikely to survive beyond a few weeks in the hospital.

However, disaster robotics is no longer focused on response but has expanded to recovery. Recovery activities consist of extricating any remaining bodies of victims, re-establishing normal operations in the community, continuity of government, and resumption of the economy. The activities are typically carried out by various local, provincial, state, and federal agencies as well as insurers and banks. Each municipality may have different priorities in rebuilding schools, hospitals, ports, and industry and there is usually no centralized authority.

The benefits of disaster robotics for the recovery phase were seen in the ongoing aftermath of 2011 Tohoku earthquake and related Fukushima Daiichi nuclear accident. The tsunami generated by the earthquake

swept thousands of people into the sea. It also severely damaged many fishing ports and scattered debris and pollutants throughout fishing areas. Teams of robotists used underwater robots to search for victims and to help re-open ports and clear fishing beds. The decommissioning of the Fukushima Daiichi facility will make use of robots, possibly some of those used in the response.

Disaster robotics is also addressing prevention and preparedness. As with recovery operations, prevention and preparedness activities are similarly distributed among many groups. It should be noted that the fire rescue and law enforcement teams will be the first responders and whatever equipment they use locally will be likely to be used at a disaster. Therefore, the disaster robotics community has begun pushing for the adoption of robots into daily use by fire rescue and bomb squads so that the responders will be familiar and comfortable with the technology [60.6]. A lesson from Fukushima was that robots built by the nuclear industry in the aftermath of Chernobyl and Three Mile Island had not been used in decades, with no one expert in their use.

60.1.2 Disaster Robot Tasks

While the overall motivation for rescue robotics is to save lives, the motivation for specific robot designs and capabilities depend on their potential tasks. The types of tasks that have been proposed for rescue robots are described below. Some of the above tasks are similar to tasks for military robots, especially search and reconnaissance and mapping, but many are unique or have a different flavor. For example, structural inspection, rubble removal, and adaptively shoring rubble are rescue specific. Tasks such as casualty extraction appear to be similar but are significantly different. Consider that a wounded soldier is unlikely to have a spinal cord injury and is likely to be in a space large enough for a human to work in, so a robot entering the area and dragging the soldier to safety is appropriate. However, a crushed victim of a building collapse is physically trapped or pinned in a small space, requiring rubble removal, and the victim's spinal cord must be immobilized before extraction; clearly victim extraction in the search-and-rescue domain is more challenging.

Search is a concentrated activity in the interior of a structure, in caves or tunnels, or wilderness and aims to find a victim or potential hazards. The motivation for the search task is speed and completeness without increasing risk to victims or rescuers.

Reconnaissance and mapping is broader than search. It provides responders with general situation awareness and creates a reference of the destroyed en-

vironment. The goal is speedy coverage of a large area of interest at the appropriate resolution.

Rubble removal can be expedited by robotic machinery or exoskeletons. The motivation is to move heavier rubble faster than could be done manually, but with a smaller footprint than that of a traditional construction crane.

Structural inspection may be either conducted on the interior (e.g., to help rescuers understand the nature of the rubble in order prevent secondary collapses that may further injure survivors) or on the exterior (e.g., to determine whether a structure is safe to enter). Robots provide a means of getting structural sensor payloads closer and in far more favorable viewing angles.

In situ medical assessment and intervention are needed to permit doctors and paramedics to interact verbally with victims, visually inspect the victim or apply diagnostic sensors, or to provide life support by transporting fluids and medication through narrow tubing. The objective is to provide telepresence for medical personnel during the 4–10 h that it usually takes to extricate a victim [60.4, 5]. The lack of medical intervention was a major problem at the Oklahoma City bombing [60.7]. Preliminary work has been conducted for victim management, most notably in telemedicine (also called *medical reachback*) [60.8], general assessment and triage [60.9], and comforting trapped victims as per the Survivor Buddy project [60.10].

Medically sensitive extrication and evacuation of casualties may be needed to help provide medical assistance while victims are still in the disaster area, also known as the hot zone. In the case of a chemical, biological, or radiological event, the number of victims is expected to exceed the number that can be carried out by human rescuers in their highly restrictive protective gear; this makes robot carriers attractive. Since medical doctors may not be permitted inside the hot zone, which can extend for kilometers, robot carriers that support telemedicine may be of huge benefit. Removing survivors, particularly from a hazardous material event where there may be many people immobilized or disoriented is another area that is getting increasing attention. The US Army Telemedicine and Advanced Technology Research Center has been leading initiatives in robots such as the Vecna BEAR for autonomous casualty extraction [60.11]. Other efforts such as those by Yim and LaCharoen [60.12] have focused on civilian casualty extraction which requires stabilization of the spine.

Acting as a mobile beacon or repeater to extend wireless communication ranges, enable localization of personnel based on radio signal transmissions by providing more receivers, and to serve as landmarks to allow rescuers to localize themselves. Active or passive

transponders such as wireless sensor nodes and **RFIDs** (radio-frequency identification) can be deployed in the field. They can also be used to support the localization of personnel, but even more to leave mission-related data such as the location of nearby victims and hazards in the field [60.13].

Serving as a surrogate for a team member, such as a safety officer or a logistics person. In this task, the robot works side-by-side with rescuers, for example, a group breaching rubble deep within the interior of a disaster may have difficulty using a radio to request additional resources because of noise. However, a team member outside of the rubble can see and hear through the robot the state of progress and anticipate needs. The objective is to use robots to speed up and reduce the demands of tasks, even if they are done by humans.

Adaptively shoring unstable rubble to expedite the extrication process. Rubble removal is often hindered by the need to adopt a conservative pace in order to prevent a secondary collapse that might further injure a trapped survivor.

Providing logistics support by automating the transportation of equipment and supplies from storage areas to teams or distribution points within the hot zone.

60.1.3 Types of Disaster Robots

Rescue robots are needed to help quickly locate, assess, stabilize, and extricate victims who cannot be easily reached. They typically do this by extending the rescuers' ability to see and act. On the ground, small unmanned ground vehicles (**UGVs**) can enable rescuers to find and interact with trapped victims in voids that are too small or too dangerous for human or canine entry. Large **UGVs** can accomplish tasks such as removing large rubble faster than humans. In the air, unmanned aerial vehicles (**UAVs**) robots extend the senses of the responders by providing a bird's eye view of the situation. In the water, unmanned marine vehicles (**UMVs**), either underwater vehicles (**UUVs**) or surface vehicles (**USVs**) robots can similarly extend and enhance the rescuers' senses.

Rescue robots can be broadly categorized into types based on *modality* and *size* [60.14], though other taxonomies that mix modality, size, and task have been proposed [60.15]. There are three modalities of robots: *ground*, *aerial*, and *marine*. The modality impacts on the basic design and capabilities of the robot. Within each modality, rescue robots can be further described as one of three sizes: *man-packable*, *man-portable*, and *maxi*. The size of the robot impacts both on the tasks for which it is suited and how soon after a disaster it might be used. In order to be man-packable, the entire robot system, including the control unit, batteries,

and tools, must fit into one or two backpacks. Man-packable robots are more likely to be used immediately after a disaster since they can be carried by responders over debris and up and down ladders into the core of the disaster, while larger equipment must wait for paths to be carved out. The next larger size is man-portable; these are robots that can be carried a short distance by two people or on a small all-terrain vehicle. Man-portable robots function in human-sized spaces such as mine tunnels. They can be used as accessibility within the hot zone improves or outside the hot zone for logistics support. Maxi-sized robots require trailers or other special transportation logistics. This inhibits their insertion into the hot zone.

Aerial rescue robots represent the most advanced robotics technology in use, and new concepts continue to emerge. Aerial vehicles can be further subdivided into *fixed wing* (plane-like), *rotary wing* (helicopters),

lighter-than-air (blimp), and *tethered* (kite) platforms. Fixed-wing UAVs typically travel long distances and can circle points of interest, while rotary-wing platforms can hover and require a small area to launch and land. Lighter-than-air vehicles may be tethered, similar to a kite. Underwater vehicles may also be subdivided into tethered and untethered platforms.

Large unmanned helicopters, such as the Yamaha R-Max, continue to be adapted for commercial rescue-and-recovery missions, including carrying heavy payloads capable of estimating the amount of rubble and debris generated by a disaster. Small fixed-wing platforms for tactical military use may have great benefit to the response community. However, UAVs are drawing the attention of agencies that control airspace and may become heavily regulated in the future. For example, the small UAV used at Haiti in 2010 flew in violation of airspace restrictions.

60.2 Disaster Characteristics and Impact on Robots

The type of disaster as well as the general pattern of activity influence the choice of robot platforms and payloads.

60.2.1 Natural Disasters

Natural disasters, such as earthquakes, tsunamis, hurricanes and typhoons, volcanoes, avalanches, landslides, and floods, present many challenges for rescue robots. Natural disasters are usually geographically distributed, perhaps affecting a 200 km or more radius around the epicenter of the event. The sheer size of the affected area presents many challenges to the emergency response. The primary impact of natural disasters is on residences, light commercial buildings, sea walls and canals, and transportation and communications infrastructure. This implies that rescuers have thousands of structures to check quickly for survivors, but those structures will be fairly small and amenable to manual and canine search. Besides the sheer volume of structures to check, communication disruptions prevent rescuers from getting timely information as to the state of transportation access and the general needs of an area. However, designing robots to meet these challenges is important because natural disasters provide the most hope of a large number of survivors. Uninjured survivors may simply be stranded and can survive for up to 72 h. Natural disasters have generally favored a bird's eye view from a UAV invaluable in establishing situation awareness or UGVs in determining *hidden* conditions of critical transportation, power, and communication infrastructure.

60.2.2 Manmade Disasters

In comparison to natural disasters, manmade disasters (such as a terrorist bombing or an industrial accident) occur in a small area, though may have significant wide-area impacts (e.g., radiation, chemical release). The challenge is often not how to see the entire external extent of the damage, but rather to see what is not visible: the interior of the rubble, the location and condition of survivors, the state of potentially dangerous utilities (e.g., electricity, gas lines) [60.14, 16, 17], and hazardous conditions such as radiation [60.18]. The communications and power infrastructure usually exist within a 10 km range and cell phones generally work outside of the directly affected area. Voids in the rubble may be irregular in shape and vertical in orientation. Wireless communications in the interior of the rubble are unpredictable, and generally nonexistent due to the large amount of steel within commercial structures, but the combination of irregular voids and sharp rubble do not favor the use of fiber optic cables. Visibility is difficult as there is no lighting and everything may be covered with layers of gray dust, further hampering recognition of victims, potential hazards, or accurate mapping. The interiors may be wet or contain standing water due to water lines, sewers, and sprinkler systems. Survivors are more likely to be in dire need of medical attention. Small ground robots that can enter deep into the interior of the rubble have been used most frequently for structural collapses, mid-sized robots for CBRNE events, and large, intrinsically safe robots for mine collapses.

60.2.3 General Pattern of Activity During the Response Phase

In order to understand how to apply robotics to disaster response (as opposed to recovery or prevention and preparedness), it is helpful to understand the general pattern of activity, which can be summarized as [60.19, 20]:

1. Responders become aware of the existence of victims. This awareness may be generated by information from family, neighbors, and colleagues, an understanding of demographic patterns (e.g., at night, apartment buildings will be heavily occupied, while during a work day, office buildings will be occupied), or by a systematic search.
2. The response command staff attempt to understand the disaster site. They investigate the site for conditions such as hazardous materials, the risk posed to the rescuers themselves, any pending threats to trapped victims, and resource restrictions such as barriers to transporting resources to the site,
3. The command staff plans the operations.
4. Search and reconnaissance teams are sent to map the situation and assess environmental conditions. Accurate estimates of the need for emergency medical intervention are highly desirable in order to optimize allocation of medication personnel in the field and to prepare ambulances and hospitals. (In the case of the Kobe earthquake, this stage took the longest time [60.19].)
5. Excavation of rubble to extract victims begins. Note that removal of rubble in search and rescue differs from construction removal of rubble, because the safety of the victims is the top priority.
6. Responders gain access to victims and apply emergency medicine in situ.
7. Victims are transferred to hospitals.
8. Field teams report activities periodically, usually at the end of the shift, and the command staff modifies or replans accordingly.

60.3 Robots Actually Used at Disasters

Small land, aerial, or marine vehicles have been used at 28 disasters and numerous local events, starting with the first use of **UGVs** at the 2001 World Trade Center collapse, see Table 60.1. The majority, 16, have taken place in the United States, followed by Japan (3), Italy (3), New Zealand (2), Haiti (1), Thailand (1), Cyprus (1), and Canada (1). The May 2013 rescue by a **UAV** guiding searchers to an injured motorist who had wandered from his car in Canada is the first reported *live save* of a person by a robot. However, as noted earlier, directly saving lives is not the only motivation for a robot. Robots have received in general high marks for completing their missions. Table 60.1 shows 37 reported deployments of robots for a disaster or well-known local incident. The deployments are grouped by major general disaster type of event: meteorological (e.g., hurricane, earthquake), geological event (e.g., earthquake, tsunami), man-made (e.g., terrorism, industrial accident), or mining (either due to a geological or a man-made event). Mine and manmade disasters are most frequent, followed by geological and meteorological events. In 7 of the 37 events, robots were present but were not used or could not reach the area of interest and thus considered not successful. **UGVs** have been used most frequently, followed by **UAVs**, and **UMVs**. While the USA initially led in reported adoptions, Europe and Asia are beginning to deploy

nearby usable equipment and materials that can be exploited, and any other barriers to a timely rescue.

3. The command staff plans the operations.
4. Search and reconnaissance teams are sent to map the situation and assess environmental conditions. Accurate estimates of the need for emergency medical intervention are highly desirable in order to optimize allocation of medication personnel in the field and to prepare ambulances and hospitals. (In the case of the Kobe earthquake, this stage took the longest time [60.19].)
5. Excavation of rubble to extract victims begins. Note that removal of rubble in search and rescue differs from construction removal of rubble, because the safety of the victims is the top priority.
6. Responders gain access to victims and apply emergency medicine in situ.
7. Victims are transferred to hospitals.
8. Field teams report activities periodically, usually at the end of the shift, and the command staff modifies or replans accordingly.

robots. This section discusses the deployments by the four disaster types, while the following section highlights the 2011 Fukushima Daiichi nuclear accident as it highlights the types of robots, missions, and challenges posed during both the response and recovery phases of a disaster.

60.3.1 Meteorological Events

Robots were used at six meteorological events and were successful at five:

- 2005 Hurricane Katrina (USA), where an Inuktun ASR Xtreme **UGV** [60.21], an Aerovironment Raven fixed wing **UAV** and a Like90 helicopter **UAV**, and a Silver Fox fixed wing **UAV** were used during the initial response phase for search, reconnaissance and mapping, and structural inspection [60.22]. Later an iSENSYS IP3 was used for structural inspection during the recovery phase [60.23]. The **UGV** searched an apartment building unsafe for human entry and the **UAVs** surveyed areas inaccessible by car. The two **UAVs** used during the response are shown in Fig. 60.1 – a battery-powered fixed-wing and a battery-powered rotary-wing (a Like90 T-Rex miniature helicopter modified for stability in high winds) **UAVs**.

Table 60.1 The modalities and numbers of robots deployed to actual disasters and whether they were successful or not

Disaster or notable incident		Disaster type of event				Robots used			Success
		Meteoro-logical	Geo-logical	Manmade	Mining	Ground	Aerial	Marine

- 2005 Hurricane Wilma, Ft. Myers, Florida (USA), where an AEOS unmanned marine surface vehicle (Fig. 60.2) and an iSENSYS T-Rex unmanned aerial vehicle were used independently and cooperatively, to assist with the recovery phase for structural inspection of buildings, docks, and piers [60.24]. The robots provided useful infor-

mation but the USV experienced significant wireless communications and GPS (global positioning system) signals near and underneath large structures.

- 2006–2010 California wildfires (USA), where the National Aeronautics and Space Administration Ikhana Global Hawk was used to provide recon-

Fig. 60.1a,b Man-packable UAVs used to search portions of Mississippi during the hurricane Katrina response: (a) an Aerovironment Raven fixed-wing UAV and (b) an iSENSYS IP3 rotary-wing UAV (courtesy of CRASAR)

Fig. 60.2 Unmanned surface vehicle exploring the bridge to Marco Island, Florida (courtesy of CRASAR)

naissance and mapping of 57 fires [60.25]. Ikhana was primarily used to gather data to develop new payloads but did contribute in 2010 to tactical response.

- 2008 Hurricane Ike, Rollover Pass Bridge, Texas (USA), where an AEOS unmanned marine surface vehicle, a VideoRay remotely operated vehicle (ROV), and a YSI Oceanmapper autonomous underwater vehicle (AUV) were used for structural inspection of the Rollover Pass bridge [60.26]. The USV was able to confirm the lack of scour around the pilings while the VideoRay could not be controlled in the high currents and the YSI AUV could not accurately preplan its path without colliding with the structure.
- 2011 Thailand floods (Thailand), where two unmanned UAVs provided reconnaissance and mapping of flood plains, allowing officials to concentrate evacuation or shoring efforts during the prevention and preparedness phases [60.27]. The UAVs are credited with mitigating damage to Bangkok and loss of life.

UGVs were present at 2004 Hurricane Charley (USA) but not used for the house-to-house inspection tasks that made up the bulk of ground operations [60.28].

60.3.2 Geological Events

Robots have been used at eight geological events (6 earthquakes, 1 landslide, 1 tsunami). They were successful at seven events:

- 2004 Niigata–Chuetsu Earthquake, where a variant of the Soryu III snake robot was used for search in collapsed houses. The snake robot was able to move into constricted passageways. Figure 60.3 shows the robot on site.

Fig. 60.3 IRS Soryu robot searching a house destroyed by the Niigata–Chuetsu earthquake (courtesy IRS)

Fig.60.6a-c Finale Emilia earthquake: (a) the UGV platform deployed in the destroyed cathedral. (b) Reconstruction of the cathedral from laser measurements, (c) and image data

- 2009 L'aquila earthquake, L'aquila (Italy), where a customized AscTec quadrotor UAV was used for structural inspection. The UAV was able to fly successfully close to buildings and windows.
- 2010 Haiti earthquake (Haiti), where a SeaBotix LBV ROV was used for underwater reconnaissance and mapping of debris in shipping lanes and an Elbit Skylark UAV was used for reconnaissance and mapping of orphanages. Both the robots provide valuable information.
- 2011 Christchurch earthquake, Christchurch (New Zealand), where an iRobot Packbot UGV and a Parrot AR.drone UAV were used for structural inspection of the Christchurch catholic cathedral [60.29]. The Packbot was successful but the UAV's camera did not face upward and the ceiling could not be examined.
- 2011 Tohoku earthquake, Sendai (Japan), where a KOHGA3 and Quince UGVs (Fig. 60.4) and a Kenaf and Quince UGVs were used cooperatively with a Pelican UAV [60.30] (Fig. 60.5) for structural inspection of damaged buildings. The robots were able to provide information to structural engineers.
- 2011 Tohoku tsunami (Japan), where nine UGVs were used for reconnaissance and mapping, and victim recovery during the recovery phase. Five different teams deployed UGV: A SeaBotix SARbot, SeaBotix LBV-300, SeaMor, and Access AC-ROV were deployed by a joint IRS-CRASAR team in April 2011 and later again in October adding

Fig. 60.7 Robots available at World Trade Center disaster. Ovals indicate the three types of robots used in the first two weeks (courtesy CRASAR)

a YSI Oceanmapper [60.31]; the IRS-CRASAR team was credited with reopening the port of Minamisanriku. Ura from Tokyo University fielded an unnamed ROV which recovered two dead bodies from an undisclosed location [60.32]. Prof. Shigeo Hirose at Tokyo Institute of Technology also created an experimental ROV and deployed with the Japanese Ground Self-Defense Forces [60.32]. IDEA Consultants (Japan) deployed their Mitsui ROV. Shibuya Diving Industry bought and used a VideoRay Pro 4, though the extent of the use is not known [60.33]. All UMVs were ROVs with the exception of the YSI Oceanmapper.

- 2012 Finale Emilia earthquake (Italy), where two custom unmanned aerial vehicles and two UGVs were used at Mirandola, Italy, for structural inspection of the exteriors and interiors of two churches that had not been entered due to safety reasons [60.34] (Fig. 60.6). The robots were able to provide information to the Italian National Fire Corps and state archaeologists.

An Inuktun VGTV Xtreme UGV was unsuccessfully deployed at the La Conchita mudslide to search for possible survivors in houses collaterally damaged by the mudslide [60.35]. The robot failed on its two runs within two minutes and four minutes, respectively, due to severe mud and thick shag carpeting.

60.3.3 Manmade Events

Robots were at nine manmade events. They were successful at eight events:

- 2001 World Trade Center collapse (USA) [60.36], where Inuktun Micro-Tracks, Inuktun Micro-VGTV, Foster-Miller mini-Talon, and Foster-Miller

Talon were used for search and reconnaissance and mapping in the interiors of the collapsed buildings (Fig. 60.7). The robots were able to penetrate farther than nonrobotic tools in spaces too small for human or canine entry.

- 2007 I-35 Bridge collapse, Minneapolis, Minnesota (USA) [60.37, 38], where two unspecified unmanned marine vehicles were used for search and reconnaissance and mapping underwater. The ROVs appeared to provide views without risking human divers in the fast moving currents.
- 2007 Berkman Plaza II parking garage collapse, Jacksonville, Florida (USA) [60.39, 40], where an Inuktun Micro-VGTV was used during the rescue phase for search and during the recovery phase an Active Scope Camera and an Inuktun ASR Xtreme were used for structural inspection along with an iSENSYS IP3 UAV for reconnaissance and mapping and structural inspection. The Micro-VGTV ruled out the presence of a survivor in areas too dangerous for a human to enter. The ASC and Xtreme provided structural forensic information that resolved legal liability and insurance coverage costs. The UAV provided imagery that led structural experts to hypothesize the cause of the collapse.
- 2010 Prospect Towers parking garage collapse, Hackensack, New Jersey (USA) [60.22], where an Inuktun VersaTrax 100 and an Inuktun VGTV-Xtreme were deployed for search. The robots were used to see vehicle information, license plates, makes and models in areas not safe for responders.
- 2011 Fukushima Daiichi nuclear accident (Japan) [60.18, 41], where seven UGVs and two UAVs were used for search, reconnaissance and mapping, and structural inspection. The robots provided damage assessment and radiological surveys without exposing workers to radiation. A UGV and a UAV were lost during the first year, but only after they provided important information.
- 2011 Evangelos Florakis naval base explosion (Cyprus) [60.17], where an AscTec Falcon and AscTec Hummingbird were used to inspect the damage to the adjacent Vasilikos power plant without requiring engineers to risk exposure to live unexploded ordinance. The UAVs were used for structural inspection. The operations were successful and led to a rapid repair of the power plant.
- 2012 Costa Concordia (Italy) [60.42, 43], where an Ageotec Perseo ROV and a VideoRay ROV, possible other unreported ROVs, were used for reconnaissance and mapping, structural inspections, and for victim recovery operations from the sunken cruise liner. The ROVs were considered essential in understanding the situation under the water.

- 2013 Missing person Royal Canadian Mounted Police (Canada) [60.44], where a Draganflyer X4-ES UAV with a thermal camera was used by the Royal Canadian Mounted Police to find an unconscious driver who had wandered from a car wreck. This is considered the first reported *live save* by a robot.

Robots were requested and present, but not used at the 2009 State Archives Building Collapse in Cologne, Germany, due in part to operator safety [60.45].

60.3.4 Mine Disasters

Robots were at 12 mining disasters. They were successful at seven events:

- 2002 Barrick Gold Dee mine, Elko, Nevada; 2004 Excel #3 mine, Pikesville, Kentucky; 2005 DR#1 mine, McClure, Virginia; 2005 McClane Canyon mine, Grand Junction, Colorado (USA), where

Fig. 60.8 The mine-permissible variant of the Wolverine robot used at the 2006 Sago Mine Disaster (courtesy of the US Mine Health and Safety Administration)

Fig. 60.9 The Inuktun VGTV-Xtreme robot being lowered into the Midas gold mine (courtesy of CRASAR)

a mine-permissible Remotec Wolverine (Fig. 60.8) was deployed the US Mine Safety and Health Administration (MSHA) used by to reopen mines that had been closed [60.46]. At the Barrick Gold Dee mine, the V-2 was deployed from the surface down a 16° slope and was able to navigate and to take continuous gas samples. At the Alliance Resources' Partners Excel #3 (coal) mine the robot was able to penetrate 230m into the mine and successfully completed the objective of providing an assessment of the situation. At the DR#1 Dixon-Russell (coal) mine the robot was able to penetrate 210 to 250 m into the mine with a slope of 18° and the robot arm was used to move and realign ceiling supports in order to progress into the mine. At the McClane Canyon (coal) mine trials were conducted to establish manipulation capabilities. In this case, the robot was tasked to close five doors and pull out timbers holding up a mine fan. The robot was generally unsuccessful with manipulation tasks.

- 2007 Midas gold mine, Midas, Nevada (USA), where an Allen-Vanguard from Fallon Naval Air Station and a Inuktun VGTV-Xtreme variant from the Center for Robot-Assisted Search and Rescue (CRASAR) were lowered into the mine and used for victim recovery [60.47]. Mine-permissible robots were not needed as the gold mine was not emitting methane. The Allen-Vanguard that was lowered into the void and found the machinery but not the victim. The Xtreme was able to penetrate 35 m vertically into the void (Fig. 60.9). The robot scanned the area where the body was recovered but did not have sufficient lighting to actually see the body.
- 2007 Crandall Canyon mine, Huntington, Utah (USA), where a custom Inuktun mine Cavern Crawler robot was deployed by US mine Safety and

Fig. 60.10 The Inuktun mine crawler robot being lowered into a borehole at the Crandall Canyon mine (courtesy of CRASAR)

Health Administration to search for missing miners (Fig. 60.10) [60.47]. The robot had to travel over 430 m through a 22 cm diameter borehole. Four attempts were made to enter the mine through two different boreholes, but only one was successful. In the fourth run, the robot was able to travel through the borehole then search about 2 m on the mine floor which was largely impassable due to the debris and drilling tailings. The robot provided no sign of the miners.

- 2010 Pike River coal mine, Greymouth (New Zealand), where two unknown New Zealand Defence Force bomb squad robots and Western Australia Water company pipeline inspection robot were used for search and recovery operations. The first New Zealand Defence Force (NZDF) robot ailed after reaching 550 m into the mine due to falling water, but was successfully restarted and moved out of the way of the second robot before running out of battery power. The first and second robots were presumed destroyed in a second explosion that ended any expectations of survivors. The

pipeline inspection robot was later used for recovery operations.

Robots were unsuccessful at two events. At the 2004 Browns Fork mine, Hazard, Kentucky, disaster, the Wolverine robot was too tall to go into the area of interest to conduct a search. At the 2006 Sago mine Disaster, Sago, West Virginia (USA), the robot was only able to penetrate about 700 m into the mine before being damaged when it accidentally was driven off the path and flipped over [60.46].

Robots were on-site but not used at three events: the 2001 Jim Walters #5 mine fire (USA) as the robot was not mine-permissible, the 2010 Wangjialing coal mine (China) presumably because the unidentified robot could not transit high water, and the 2010 Upper Big Branch mine (USA) where the restricted confines posed too great a risk of failure. Robots were requested for the 2010 San Jose Copper-Gold mine (Chile) and the 2011 San Juan De Sabinas coal mine (Mexico) disasters but robots were not small enough and thus were not sent.

60.4 Robots at the Fukushima-Daiichi Nuclear Power Plant Accident

The Fukushima-Daiichi nuclear power plant accident merits special attention because robots have been used for both the response and recovery phases. The use of robots have been sustained over months and years, and a wide variety of robots have been used.

Control over the reactors at the Fukushima-Daiichi nuclear power plant was lost on March 11, 2011, after a 14 m high tsunami from the Eastern Japan Earthquake submerged the facility. Units 1–3 melted down, hydrogen exploded at the high floors of nuclear reactor buildings of Units 1, 3, and 4, and huge amounts of radioactive materials were released to the wide area centered by Fukushima Prefecture. Robots were used during the prolonged response phase for assessment of the emergency situation and mitigation of the event by recovering the cooling systems to enable a cool shutdown. After four months, the immediate response turned to preparation for decommission as the reactors were stabilized. The recovery phase requires operations in the contaminated area; therefore, many robotic systems have been, and are continuing to be, used for minimizing workers' exposure to radiation by substituting for human operations. In the first year, ground and aerial robots were used for exterior operations outside the buildings and ground robots for interior operations inside the reactor buildings.

60.4.1 Exterior Operations

Robots were used outside the buildings and on the grounds by different teams for four applications: debris removal, structural inspection, radiological surveys, and mitigation efforts.

Debris Removal by Unmanned Construction Machines

There was a large amount of contaminated debris outside the building producing a high dose rate of a few hundred mSv/h, preventing workers accessing the buildings. Debris removal operations were conducted starting April 1, 2011 for nine months using an adaptation of unmanned construction robot machines had been developed for the restoration work after the *Unzen Fugen-dake Volcano* eruption in 1991 (Fig. 60.11). Debris was gathered by two backhoes and a bulldozer, with wireless teleoperation, then loaded to containers on two remote-controlled crawler dump trucks, and carried to storage yards of contaminated materials. The crawler dump trucks were teleoperated from a remote operator car, with command and control signals and data from camera and sensors transmitted via a remote-controlled radio relay car. Seven camera cars were connected to the system by wire, and external image views supported the task execution. As

Fig. 60.11a,b Unmanned construction machines used at Fukushima-Daiichi (courtesy of Unmanned Construction Machines Association)

a result, debris of 20 000 m³ was removed from the area 56 000 m² wide, and the radiation level reduced significantly to safely accessible level for the workers.

Structural Assessment and Radiological Surveys from T-Hawk UAV

A team led by Westinghouse used Honeywell T-Hawks from April 10, 2011, to the end of July, 2011 (Fig. 60.12). The team flew approximately 40 missions with two objectives originally. One was to investigate the state of the reactor and turbine buildings and to acquire video of the general area in order to support initial assessments of the incident and to help plan for debris removal. The second was to take radiological samples to produce a survey map. The objectives later expanded to off-site debris field survey, survey of the coastal breakwater structure, a gamma radiation survey at specific locations of interest to TEPCO, and airborne-particulate sampling (flying into plumes) at select locations.

Radiation Source Measurement by Gamma Cameras

The Japan Atomic Energy Agency (JAEA) developed a robot control car *TEAM NIPPON* with a gamma camera, a 3-D camera, a thermo camera, and a QinetiQ Talon robot that were provided by Idaho National Laboratory, a US federal laboratory that conducts research in nuclear reactors, in collaboration with Tohoku University. It was used from May 5, 2011 for measuring radiation of the outdoor debris, and provided visualized data as shown in Fig. 60.13 [60.18, 41].

Remote Control of Concrete Pumping Cars

Concrete pumping cars had been used for pouring water from outside in order to cool used-fuel pools on the

top floor of the exploded nuclear reactor buildings. In order to reduce the radiation exposure of workers who control their long arms, the cars were fitted for remote teleoperation by using remote controllers, cameras, and wireless equipment on May 2011.

60.4.2 Interior Operations in Nuclear Reactor Buildings

UGVs continue to be used for operations in the interior of the reactor buildings. UGVs were used to survey the interiors (iRobot Packbot, IRS Quince), monitor for gamma radiation (JAEA J-3), remove debris (QinetiQ Bobcat and Talon, Brokk), and experiment with decontamination (iRobot Warrior).

Survey of Nuclear Reactor Buildings by PackBots

On April 17, 2011, TEPCO workers and six engineers from iRobot used two donated PackBots to open the double hatch doors of Units 3 and 1, providing the first entry into those buildings (Fig. 60.14). The TEPCO workers carried the robots to the front of the hatch, and pointed an antenna to the robots from the glass window of the hatch. Based on the readings of radiation dose rate, temperature, humidity, and gas concentration, humans were allowed to enter the nuclear reactor buildings to begin the cool shutdown process. On the following day, the same mission was tried in Unit 2, but the PackBot could not complete it. The camera window of PackBot misted over under high humidity, because the vapor from boiled water on the basement floor did not escape from the building. Prior to the actual operations, TEPCO workers were intensively trained on remote teleoperation starting on March 24, 2011, and the scenario was verified in Unit 5, which was not dam-

Fig.60.14a,b Operations of PackBots in Unit 1 (courtesy of TEPCO)

aged. The PackBots continue to be used for monitoring and light tasks in the buildings.

Survey of Nuclear Reactor Buildings by Quince

The Quince robot was used in addition to the iRobot Packbots in June, 2011 (Fig. 60.14), and is now being used in cooperation with the Packbots for various missions as only Quince could climb the steps to the upper floors. Quince had been developed for CBRNE disaster response by a team from the International Rescue Sys-

tem Institute including Chiba Institute of Technology and Tohoku University. One unit of Quince was lent to TEPCO for free after radiation-proof test, wireless communication test, intensive refinement of reliability, and training exercises of operators [60.48]. Quince has been used for surveillance of the nuclear reactor building since June 24, 2011. On July 8, it entered Unit 2 and measured the dose rate on the second and third floors, then sampled dust for identification of nuclide (Fig. 60.15). On July 26, valves and pipes of a spray

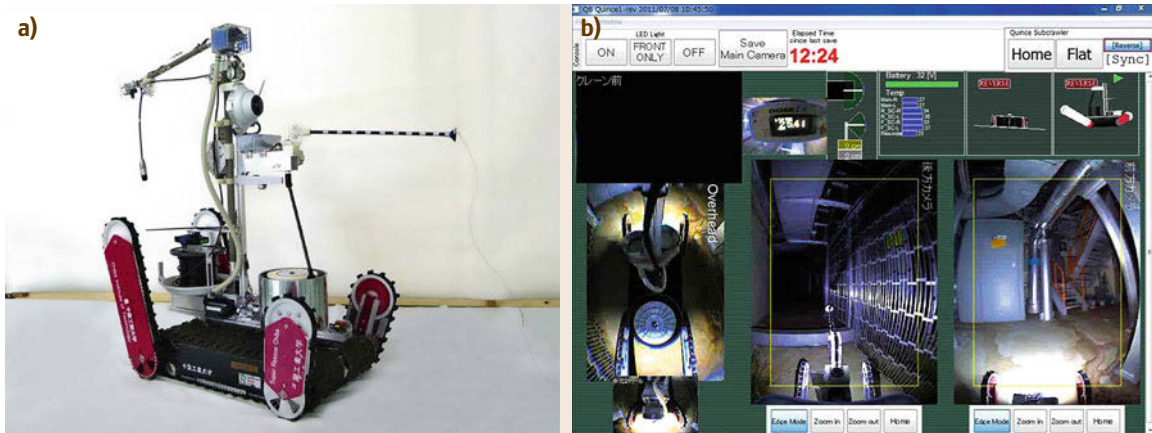

Fig.60.15a,b Quince at Fukushima: (a) robot platform and (b) its operator station image captured in the mission on July 8, 2011 (courtesy of TEPCO)

cooling system were visually inspected by the high-density camera and dose rate was measured in Unit 3. Redundant cooling system was established on the basis of these data. On October 20, Quince surveyed fully on the third floor of Unit 2, then climbed the stairs up to the fifth floor (operation floor) for monitoring. The high dose rate, condition of the crane, etc. were investigated on the high floors at first. However, it stopped on

the third floor on its return home because its communication tether was hooked and cut. If Quince had not been applied, it would have been delayed to examine situation of the upper floors, and the risk would have become higher because of late cool shutdown. Quince 2 and 3 were remodeled and lent for free of charge to TEPCO from 2012, and are used in cooperation with PackBots for various missions.

60.5 Lessons Learned, Challenges, and Novel Approaches

The experiences with disaster robotics since 2001 provide key insights into technical challenges, such as mobility, communications, sensing, control, and human factors, but also into sociotechnical issues such as training and procedures for transporting and decontaminating robots. This section highlights the general lessons learned and the fundamental problems posed in mobility for UGVs, UAVs, and UMVs, communications, control, sensors and sensing, power, human-robot interaction, multirobot team coordination, and other issues.

60.5.1 Mobility: UGVs

Mobility remains a major problem for all modalities of rescue robots, but especially for ground vehicles. The challenges for ground robots stem from the complexity of the environment, which is an unpredictable combination of vertical and horizontal elements with unknown surface characteristics and obstacles. For example, at Fukushima, the original configuration of the iRobot Packbot could not climb the steep metal staircases. In other cases, a robot could not cross a catwalk or climb

stairs due to rubble and the lack of confidence that the robot could negotiate the debris. Robots such as the Inuktun VGTV-Xtreme at the La Conchita mudslides could not handle the terrain, while the Allen-Vanguard was too heavy for vertical entry into the Midas gold mine.

The field is currently lacking any useful characterizations of rubble to facilitate better design. However, even without a complete understanding of rubble environments, it is clear that more work is needed in actuation and mechanical design as well as in algorithms that would enable the robot to adapt its mobility style to the current terrain (also known as *task shaping* [60.49]).

The state of the practice in UGVs for disasters are polymorphic tracked vehicles, with a movement toward tracked robots with manipulators (e.g., the Wolverine used for mine disasters, the robots at Fukushima) and two instances of snake-like robots (Niigata-Chuetsu earthquake, Berkman Plaza II collapse). Wheeled platforms are severely limited by the roughness of the terrain and the need to overcome obstacles, steps, ramps, but combination wheeled and tracked vehicles

Fig. 60.16a,b Examples of legged and crawler robots. (a) Hexapod (legged) robot from the RHex project traversing a portion of the National Institute of Standards and Technology (NIST) test bed (courtesy of R. Sheh) and (b) Terminatorbot being tested in rescue test bed (courtesy of R. Voyles)

are commercially available. Basic research in legged robots (Chap. 48), wheeled robots (Chap. 49), micro/nanorobots (Chap. 27), and manipulators will benefit disaster robotics.

Free serpentine robots such as the Soryu III used at the rubble at the Niigata–Chuetsu earthquake provide a fundamentally different style of mobility, while *fixed-based* snakes can be used in tandem with a more traditional platform as a highly flexible sensor manipulator [60.50]. Examples of both types of snake robots are shown in Figs. 60.3 and 60.19.

In order to overcome the difficulties posed by unknown terrain, novel legged robots and crawler robots have been proposed. In addition, some types of crawler robots can climb walls and reach locations that would otherwise be very hard to reach. Legs are interesting because they exploit biomimetic principles. The RHex hexapod robot [60.51], proposed for search and rescue among other potential applications, is shown in

Fig. 60.16 climbing random step fields. Crawler robots such as the Terminatorbot [60.52] use their arms or legs to pull themselves through the rubble. The Terminatorbot is designed to withdraw itself into a cylinder that can be inserted through one of the small boreholes commonly drilled by responders to get through walls, then open up and begin moving. Other types of crawlers include lizard- or gecko-like robots that adhere to walls; these types are promising but have not been tested for the dusty, wet, and irregular conditions found in disasters.

Another novel concept for UGVs is that of *smart* tools, particularly lifts that can help stabilize collapsed structures during extrication [60.53, 54]. Extrication is one of the most time-consuming activities in rescue. Rescuers must proceed cautiously when removing rubble in order to prevent secondary collapses or slides that would further injure the survivors. Experiments suggest that roboticized lifts or shoring mechanisms would be able to sense and respond fast enough to small movements in the rubble to adaptively maintain stability [60.54].

60.5.2 Mobility: UAVs

UAVs are increasing in popularity with responders, possibly because on demand aerial access is a unique capability. Aerial vehicles, particularly helicopters, are vulnerable to wind conditions near (or in) structures and obstacles such as power lines, trees, and overhanging debris. A UAV at Hurricane Katrina hit a power line.

Novel ideas include a plane with the size of a person's hand that can fly indoors and planes with foldable wings, making it easier for responders to carry them. Quadrotor helicopters appear far more stable and easier to pilot; a design that balanced the larger size of a quadrotor with an appropriate payload could make UAVs more assessable to nonpilots. Another exciting direction is hybrid platforms that can change from fixed-wing operations, covering large distances, to rotary-wing operations, flying near or inside buildings [60.55].

60.5.3 Mobility: UMVs

Surface and underwater vehicles have to contend with swift currents and floating or submerged debris, placing significant demands on agility and control. As seen at the Tohoku Tsunami, AUVs could not be used due to the possibility of colliding with flotsam. Teleoperated ROVs can function in such conditions but have a risk of tethers becoming tangled or caught, as seen at the Tohoku Tsunami and the Hurricane Ike response.

60.5.4 Communications

Robots rely on real-time communications for teleoperation and for enabling responders to see what the robot is seeing immediately. Ground robots communicate either through a tether or via wireless radio. Aerial and surface robots are wireless, while underwater rescue robots are controlled via a tether. The communication bandwidth demands of all modalities are generally high due to the use of video imagery, and the tolerance to communications latency is low due to the control needs. In addition to communications between the tactical rescuers and their robots, it is difficult to report or transfer critical information provided by rescue robots to the strategic enterprise. Disasters typically destroy the communication infrastructure, both telephones and cellular phones, and alternatives such as satellite phones become saturated by response agencies.

Wireless communications with robots remain problematic. Operations below ground or near structures interfere with the physical propagation of radio signals. As shown in high-fidelity **USAR** response exercises, ad hoc wireless networks established by responders are likely to become quickly saturated, with no way of establishing priority over information. At the World Trade Center, data from the Solem robot deployed in the interior of building **WTC4** returned totally black frames for 1 min 40 s of the 7 min run before wireless communications were totally lost and the robot was abandoned [60.36]. In addition, many wireless robots use lossy compression algorithms to manage bandwidth, which interfere with computer vision techniques, and/or connect through insecure links, raising the possibility that news media might intercept and broadcast sensitive video of trapped victims.

Rescue robots working underground, either for **USAR** or mine rescue, have two alternatives to wireless communications: either operate with a tether or deploy repeaters to maintain wireless communications. Many wireless robots now can be purchased with a fiber-optic tether; however, these tethers are fragile and may break or tangle, as seen at several mine disasters. The fiber-optic tether may also tangle with the safety rope used to support the robot during vertical drops. Data for the World Trade Center deployments indicated that a dedicated person was required to manage the tether but that 54% of tether management operations were to allow the robot to reach a more favorable position or to recover the robot after its mission [60.36].

At Fukushima, outside the buildings, allocation of wireless frequencies and accommodation of communication methods were extremely difficult, and usage of some robot frequently affected the other robots. Inside the buildings, wireless communication was sometimes

unstable, and a few robots could not return. Operators always had to pay attention to radio field strength and cable tether handling.

Majority of **UGV** operations have used tethered robots, with the only wireless robot used at the **WTC** disaster being lost and the wireless **NZDF** robots creating significant problems with intermittent failures. Hybrid communications, in which a robot is primarily on a tether and then operates for short distances over a local wireless link before reconnecting to the tether, appear to be attractive.

A novel approach is to use other robots as repeaters, either stationary or mobile, to facilitate the establishment of communications and sensor networks. As repeaters for mobile ad hoc networks, robots on the land, sea, and air can extend the range and throughput of wireless networks [60.56]. A recent US Defense Advanced Research Projects Agency program, **LANDroids**, developed a set of small robots that acted as mobile repeaters for a larger robot entering the interior of a structure or tunnel. Aerial vehicles are particularly attractive as they can provide larger relay ranges while providing a bird's eye view of the disaster. However, a **UAV** does not always have to move: a tethered blimp or kite can support a sophisticated payload with no maintenance or support for days [60.57, 58].

60.5.5 Control

Robot control can be subdivided into *platform control*, which is usually considered by control theory, and *activity control*, which generally falls under the purview of artificial intelligence. Rescue robots are challenging both for traditional control and for artificial intelligence. The high degree of mechanical complexity of all modalities and the demands of the environment present major challenges for control theory. In all report events, the robot's activity was handled by teleoperation; a human is needed to direct the robot and to perform mission sensing. The well-documented problems of manual teleoperation (Chap. 34) argue for increasing autonomy [60.59], both in terms of navigation.

Navigational autonomy has been the primary focus within the disaster robotics community and efforts generally fall into the following three categories:

- *Simultaneous localization and mapping (SLAM)*: **SLAM** is needed for the search and reconnaissance and mapping tasks. Whereas **SLAM** in office-like environments appears to be almost solved, the application of same techniques in harsh and unstructured environments turns out to be extraordinarily difficult or even impossible. One strong limitation of current mapping solutions is their inability to pro-

vide an accurate 3-D model of the environment at high data rate. For USAR such a solution has to cope with the reflection properties of debris, smoke due to fires, and the spectrum of lightning conditions. The solution also needs to be low cost in terms of required onboard CPU (central processing unit) computation and payload, due to weight and power limitations. Existing solutions rely either on automatically inclined [60.60, 61] or constantly rotating 2-D (two-dimensional) laser scanners [60.62]. In contrary to 2-D maps, which are typically generated in real time [60.63], 3-D maps are updated at low rates on the order of seconds due to the limited data rate of inclined or rotated laser scanners.

- *Exploration, planning, and path execution:* The central question in autonomous exploration is: *given what you know about the world, where should you move next to gain as much as many new information as possible?* [60.64]. Autonomous exploration can be subdivided into determining where to go next, how to plan the path to get there, and how to execute that path safely.

The primary approach to exploration is to use a frontier-based exploration algorithm is to gain new information by moving to the boundary between open space and unknown territory, denoted as *frontier*. Frontier-based exploration, either based on 2-D [60.64] or 3-D [60.65] map representations, is an efficient technique that has been successfully deployed together with SLAM techniques for exploration in NIST-like USAR arenas [60.66].

The objective of path planning in harsh environments is not necessarily to generate the shortest but the safest path. Wirth and Pellenz introduced an exploration strategy and path planner that utilizes occupancy grid maps for combining the distance transform and the obstacle transform (when planning to several frontier cells at the same time [60.67] in order to select the safest alternative consisting of target location and path to reach the target.

Most methods for motion planning in USAR are still limited to static environments that can efficiently be represented in 2-D. However, since robots operate on rough terrain that may suddenly shift it is important to consider the shape of the surrounding terrain and its potential impact when moving. Several researchers have introduced solutions with short-term planning look ahead that execute specific robot behaviors with respect to the current situation of the robot. Okada et al. introduced an autonomous controller for tracked vehicles that is based on continuous 3-D terrain scanning [60.68]. Magid et al. introduced a system for keeping the

robot maximally stable at every step of its path while allowing the vehicle to loose balance in a controlled manner for facilitating safe climbing over debris [60.69]. Sheh et al. developed a method for *behavioral cloning*, a type of learning by imitation that produces control rules that clone the skills of an expert human operator [60.70]. Dornhege et al. introduced the concept of behavior maps, which link certain robot behaviors on rough terrain such as climbing over stairs and obstacles, to structures detected from 3-D point clouds in real-time [60.71].

- *Object recognition and scene interpretation:* The search, reconnaissance and mapping, and structural inspection tasks for disaster robots would benefit from autonomy. They currently rely on humans to manually scan video feeds for signs of survivors, reconstruct the scene, identify potential hazards, and accurately comprehend the integrity of structures. To this end, Andriluka et al. evaluated various state-of-the-art techniques for vision-based victim detection from UAVs [60.72]. They concluded that by combining multiple weak models the overall detection reliability can be increased. Kleiner and Kummerle presented an approach for detecting victims based on several visual features such as body motion, skin color, and body heat [60.73]. Hahn et al. presented an approach for improving victim detection from low-cost thermal sensors by computing heat distributions while exploring an environment [60.74]. Birk et al. developed a system for recognizing humans from images taken by an infrared camera that considers plausible body shapes and postures [60.75].

60.5.6 Sensors and Sensing

Sensors, and sensing, pose the greatest mission challenge; without adequate sensing, a robot may be in an area of interest but be unable to navigate or to execute the larger mission. The physical attributes of a sensor (size, weight, and power demands) impact on whether it can be used with a particular robot platform. Currently sensors are not interchangeable between platforms; standards are needed for footprint sizes, mounting, connections, and display space.

The functionality of a sensor depends on the modality and mission [60.16]. The primary sensor missing from all robot modalities operating outside of water is a miniature range sensor. With a miniature range sensor, the success in localization and mapping seen with larger robots would be transferable to rescue robots. The sensor payloads for other missions depend on those applications; however, two sensor needs for USAR are

particularly noteworthy. One is a detector that can perceive victims obscured by rubble; current radars have not been reliable in mixed rubble. Another needed sensor is one that can tell if a victim is unconscious but alive without touching the victim. A robot may be able to see a victim, yet not be able to crawl to the victim and make contact or scrape away enough dirt or clothing to take a pulse. Stand-off detectors such as millimeter-wave radars and gas detectors appear promising but have not been validated at this time.

Smaller, better sensors are not sufficient; improvements in sensing algorithms are also needed. At this time, humans are expected to interpret all sensing data manually in real time. This is a daunting task for many reasons. Human performance is handicapped by physiological factors introduced by sensing through a computer display (also known as computer mediation), the location of sensors at viewpoints low to the ground, generally restricted fields of view, and fatigue. The modality output itself may also be nonintuitive, such as ground-penetrating radar. However, autonomous detection and general scene interpretation is considered well beyond the capabilities of computer vision. This presents a case where neither the human nor the computer can accomplish the perceptual task reliably and argues for investigation into human–computer cooperative techniques for perception. Algorithms that enhance the image for human inspection, supplement depth perception, or cue interesting areas are within the reach of computer vision.

60.5.7 Power

The robot modality and mission poses distinct challenges for power, although only one robot, the [NZDF](#) robot at the Pike River mine, has caused a failure. In general, battery power is preferred over internal combustion because of the logistics difficulties in transporting flammable liquids. While the requirements of each rescue robot application is largely unknown, a partial understanding is emerging of the power profile. For example, the operation tempo of a ground vehicle operating underground is on the order of 3–4 runs, each around 20 min in duration, over a 12–14 h shift, with the robot kept on hot standby for the majority of the shift. Rotary-wing aerial vehicles for tactical reconnaissance and structural inspection show an operations tempo of 5–8 min per face of a building, while fixed-wing vehicles are airborne for less than 20 min. Other rescue missions, such as wilderness search and rescue, will have different requirements but the need for batteries over internal combustion and for determining the power profile is the same.

60.5.8 Manipulation

Manipulation has been required for mine remediation (e.g., DR#1 and McClane Canyon mines) and at the Fukushima nuclear accident, but overall manipulation has failed in at least one task per mission. Furthermore, manipulation is almost always time consuming as all reported instances have been teleoperated. Robots with manipulators (such as that seen in [Fig. 60.17](#)) extend the capabilities of ground vehicles by allowing the robot to sample the environment, interact with survivors, move light obstructions, and add unique camera viewpoints. However, the manipulator extends the volume of the robot, impacting navigation. The arm is often at risk of being damaged in confined spaces being hitting on overhanging rubble. Manipulators also add to the control and mechanical complexity of the robot.

Fig. 60.17a,b Examples of tracked robots with manipulator arms that have been used for disasters or rescue competitions. **(a)** View from Foster-Miller Talon at the WTC of its arm (courtesy of [CRASAR](#)) and **(b)** teleMAX by Telerob at the Rescue Robotics Camp (courtesy of R. Sheh)

60.5.9 Human–Robot Interaction (HRI)

According to the analysis by *Murphy* [60.22], over 50% of the robot failures during a disaster are due to human error, which emphasizes the importance of human–robot interaction. For the purposes of this chapter, **HRI** concerns fall into five topics: ergonomics, system design, human–robot ratio, situation awareness, and training.

One aspect of **HRI** is ergonomics. The Fukushima nuclear accident highlighted how personal protection equipment (e.g., full-face mask and rubbery gloves) precluded workers from performing delicate work and efficient task execution.

Another aspect of **HRI** is the larger system design. At the Fukushima nuclear accident, workers had to carry the robots to the point of entry; this sometimes increased the total radiation exposure of workers, which was clearly not the purpose of the robot. The inability to transport certain robots caused them to be excluded from the World Trade Center disaster.

The number of operators per robot has been the subject of debate, though *Murphy* and *Burke* in [60.76] offer a formula based on their comprehensive field studies for computing the baseline human-to-robot ratio

$$N_{\text{humans}} = N_{\text{vehicles}} + N_{\text{payloads}} + 1.$$

The idea is to then justify why a smaller ratio would not increase unacceptable risk to the mission. For example, a **UGV** often does not need a safety officer, while a **UAV** does under most regulations. One way to decrease the number of people is to reduce their workload, such as by increasing the navigational autonomy from normal operations. However, *Murphy* and *Burke* document that if the unmanned system encounters a problem and returns control to the operator, the operator is unlikely to be able to react fast enough to avoid a crash, collision, or severing of a tether. This problem has been documented in aviation safety with initial problems with auto-pilots, where it is generally referred to as the *human out of the loop control* (**OOTL**) problem. The **OOTL** problem should not be interpreted as discouraging autonomy but rather encouraging a more comprehensive consideration of how autonomy will be handled in all conditions, not just normal operations.

Related to the number of operators is how well they can maintain situation awareness. Situation awareness is defined by *Endsley* in [60.77] as

the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning and the projection of their status in the near future.

Drury et al. [60.78] have defined types of situation awareness within search and rescue based on an analysis of RoboCup rescue tasks, while *Casper* and *Murphy* [60.79] and *Burke* et al. [60.80] have examined operator situation awareness in technology insertions. User interfaces are a key component in facilitating situation awareness. In rescue robotics, user interfaces are generally primitive and work through the operator's visual channel to provide robot, task, and situation awareness of the state of the robot, task progress, and the general operational environment. To highlight the importance of user interfaces, one robot at the World Trade Center was rejected because of the complexity of its interface [60.36]. While the user interface for fieldable rescue robots primarily display the video output from the robot, experiences from RoboCup rescue suggest that a good interface will both facilitate commanding the robot (inputs) and will provide three types of information (outputs):

- The robot's perspective: camera view(s) from the robot's current position, plus any environmental perceptions that enhance the general impression of telepresence
- Sensor and status information: critical information about the robot's internal state and its external sensors
- If possible, a map: a bird's eye view of the robot situated in the local environment.

The Fukushima nuclear accident illustrated the importance of training, as training of operators with using simulated mockups took over a month. The current state of the practice is for responders to receive training from the robot manufacturer on how to operate and maintain the robot, ignoring concepts of operations for actual scenarios. Training is a related issue in human–robot interaction [60.81]. Rescue workers have limited time compared with military operations to learn about robots and few opportunities to practice. While a bomb squad or special weapons and tactics team for law enforcement may be called out several times each month, a rescue team may be called out only a few times each year. For the near future, rescue workers may not have had prior training or experience with a robot prior to the disaster and be expected to use prototypes with only *hasty* training.

60.5.10 Multirobot Team Coordination

Multirobot teams of robots that cooperate with each other or work on the same objective have already been used or demonstrated for response and recovery activities at Hurricane Wilma (**UMV-UAV**) [60.24], the Tohoku tsunami (**UMV-UMV**) [60.31], and the To-

hoku earthquake (UAV-UGV) [60.30]. These have all been heterogeneous teams though homogeneous teams have been entered at the RoboCup rescue competition [60.82]. Only one of the three deployed teams was explicitly coordinated, where a Quince robot carried a Pelican UAV at the Tohoku earthquake and conducted cooperative mapping of the interior of a damaged building [60.30]. The current research approach to teams is focusing on adopting techniques from artificial intelligence for either centralized or distributed coordination.

Multirobot teams not only offer the possibility to field diverse capabilities, they also exhibit increased robustness due to redundancy, and superior performance by parallel task execution [60.83]. This latter aspect is as important as the first one, since the time to complete a rescue mission is of vital importance. For example, one fundamental problem when searching for survivors is to efficiently coordinate a team performing space exploration. However, the IRS-CRASAR team at the Tohoku tsunami response uncovered implicit assumptions about parallel task execution that limited performance [60.31]. The coordination of several autonomous units in search and rescue operations still represents an open issue. One reason is the fact that the higher number of degrees of freedom imposed by the robot team requires a larger number of trained human operators, which in turn makes the deployment during a rescue mission more complicated. Certainly, the number of required operators also depends on the quality of autonomous perception and decision-making of each single system. Therefore, in order to reduce the human-to-robot ratio in the field, autonomous capabilities as well as autonomous methods facilitating team coordination are needed. There are several existing techniques for team coordination in USAR, which can generally be separated into centralized and decentralized approaches.

There are three novel types of teams being pursued for disaster robotics. One type is swarms. Researchers such as [60.84] have discussed the possibility of using cost-effective, insect-sized robots to penetrate deep within a pancake building collapse and then signal the presence of a victim. One of the key features of swarm approaches is that they can scale up easily. The insect swarm scenario leaves hard problems like control, sensing payloads, localization of the victim, and communications to the imagination, but is certainly a worthy concept. However, some of the search algorithms used by insects may be adapted to single robots, for example, win-shift win-stay sampling exhibited by bees may be useful for search [60.85]. A second type of team, similar to swarms, is motes, where aerial vehicles that drop intelligent sensors called motes.

A third type of team is a hybrid robot-animal team, where search dogs carry roboticized cameras (dog-cams) [60.86] or wiring rats with controllers. Attaching cameras to search dogs has been explored for several years and such a system was used at the World Trade Center. The concept does not compete with robots, as robots are used to enter places canines cannot. The canine team handlers have generally objected to dog-cams because the cameras and communications gear interfere with the dog's mobility, pose the hazard of snagging, and the dog cannot be readily commanded to stop at points of interest beyond the line-of-sight of the handler (dogs use visual cues as commands, more than audio). However, there is less objection to placing nodes in a rat's brain to stimulate and drive the rat into a void while carrying a camera or other sensors [60.87]. The motivation for a robot rat stems in part from the rat's mobility and relative low value. While the technical feasibility of a robot rat may be within reason, assuming advances in wireless communications, the response community has been lukewarm toward the idea [60.88]. Unlike rats, robots can be kept in storage for years and can penetrate through pockets of fire or areas with no oxygen. A robot rat has all of the limitations of dog, including the problem of a handler becoming too emotionally attached, and is likely to scare a trapped survivor just as much as the other rats that swarm a disaster. The conventional wisdom is that, if the sensors, wireless, and power systems can be miniaturized and operate reliably enough to control a rat deep within rubble, those systems will enable responders and robots to work without the rats.

60.5.11 Other Issues

In addition to the challenges by the functional subsystems of a robot, three other issues should be considered.

Robots must be reliable. As noted in the discussions of the Pike River mine explosion and the Fukushima nuclear accident, *failure of a robot can obstruct the mission execution or cause it to completely fail*. A robot failing not only means the mission did not get performed, but could prevent other robots from carrying out the mission. For example, a robot getting stuck on the stairs would pose a navigational hazard to other robots or to workers in bulky safety gear. Such risk has to be minimized by thorough analysis and preparation beforehand.

Robots must be suitable for the environment. In at least two mine disasters, robots could not be used because they were not explosion proof – yet needed to be used in an explosive atmosphere. At Fukushima, robot operators had to be concerned with potential

damage of semiconductors by total dose of radiation, which could affect not only CPU and image sensors but also various components using semiconductors such as engine, battery, etc. Monitoring of the total dose using a dosimeter was necessary.

Robots must be decontaminated. Radiation contamination at Fukushima was a serious issue because it

caused radiation exposure of workers in maintenance and battery exchange. However, UGVs at the World Trade Center collapse were exposed to raw sewage and body fluids. Decontamination has been discussed in standardization procedures but few platforms are built to be completely cleaned or to be easily cleaned without exposing the human.

60.6 Evaluation

Disaster robotics is still an emerging field and methods for evaluating a rescue robot or the larger mixed human–robot system are still forming. *Murphy* in [60.22] provides an analysis of the performance of disaster robots at 34 events. Evaluation is largely centered around the US government National Institute of Standards and Technology (NIST) efforts to standardize rescue robots for adoption by US responders via originally a standard test course and more recently a set of standard test methods. Each standard test method is an inexpensive, reproducible prop that tests a single capability; for example, Fig. 60.18 shows a prop designed to test a robot's ability to traverse rough terrain represented by a wooden *step field*. The standard test course and methods are duplicated via the USARsim computer simulation, and at least two sites, NERVE and SWRI, have physical testbeds consisting of the NIST standard test methods – though other physical testbeds such as Disaster City exist. The test course and methods have been used since the late 1990s for the RoboCup rescue and AAI mobile robot competitions. This effort is being conducted through ASTM and thus, even though it is largely driven by the US, will likely result in an international standard that may be adopted by other countries.

60.6.1 Computer Simulations for Rescue Robotics

Computer simulations provide a low-cost mechanism to explore the larger behavior of a robot or system. Generally, computer simulations provide high fidelity for testing software execution, but their physical fidelity depends on the physics engine. Simulating sensors and the complex environments produced by a disaster is difficult and is rarely accurate enough to test perceptual algorithms. At the time of writing, two readily available computer simulations exist for exploring the strategic and tactical applications of rescue robots within the RoboCup rescue framework [60.89], the *RoboCup rescue simulation project* [60.90], and *USARSim* [60.91]. These simulations are well understood, accepted, open-

source, and free; as such, they should be useful for most researchers or practitioners interested in ground-based rescue robotics.

The RoboCup rescue simulation project is used in the RoboCup rescue simulation league to study agent-based approaches to strategic planning for the disaster response. The simulator assumes a strong centralized response capability that is not necessarily the case for all countries or regions; the United States, for example, relies on a highly distributed organization that obviates many centralized coordination schemes. Although the simulation is focused on strategic decision making, particularly dynamic resource allocation, it does support the examination of how robot resources might be allocated during a disaster and how data from a robot might be propagated through a system. It permits the simulation of monitoring of disaster damage from reports by humans, distributed sensors, and robots and can simulate complex interactions such as telemedicine.

USARSim is a computer simulation developed by the University of Pittsburgh for physical robot simulation in disaster situations [60.91]. The simulation replicates the NIST standard test bed for search and rescue and permits efficient prototyping and testing of robot design and most aspects of control software. It uses Unreal game engine for handling physics and graphics, and virtual robots have capability of sensing (image, laser range finder, etc.) and actuation (wheel, motor, etc.) with data processing (image recognition, SLAM, etc.) in artificial environments. In 2006, the RoboCup rescue competition created a simulation league using this environment.

60.6.2 Physical Test Beds

Physical test beds provide a more realistic venue than a computer simulation for evaluating rescue robots, but may not be available to researchers, too expensive to use or to travel to, or not adequately capture some key aspect of a disaster. Physical test beds generally fall into three categories: *test beds developed for the fire rescue*

Fig. 60.18a–c View of the **NIST** standard test bed for search and rescue used by RoboCup Rescue. **(a)** View of overall test bed, **(b)** dummy representing a victim, and **(c)** a step field challenging robot mobility (courtesy **NIST**)

community, test beds developed for the robotics community, and the **NIST** standard test bed for search and rescue.

Fire rescue training test beds occur throughout the world and are used to train human firefighters, rescue specialists, and canine teams under highly realistic conditions. The Texas A&M Engineering Extension Service's Disaster City complex has 52 ac devoted to

Fig. 60.19 A **CMU** (Carnegie Mellon University) fixed-base snake being tested at a facility in California (courtesy H. Choset)

representative structural collapses, ranging from multi-story commercial building to wooden housing. Disaster City is the site for the **NIST** Response Robot Evaluation Exercises. The **NASA** Ames Research Center's Disaster Assistance Response Team facility at Moffett Field has hosted several events as well. In general, fire rescue test beds are constructed from construction and sewer debris, can introduce smoke and some simulants, and pose challenging mobility conditions, but vary in terms of fidelity. In many test beds, the density of the debris does not contain the actual amount of metals in a real collapse. This can lead to optimistic reports of success of sensors and wireless communication devices. The test beds, being designed for human training, do not replicate the conditions under which a ground robot would be used. The terrain is generally on the exterior of the rubble and does not exercise the robot in confined or vertical spaces. Depending on the size of the facility, the test bed may or may not be suitable for evaluating **UAV**s. An example of a fire-training test bed appeared earlier in Fig. 60.19.

Physical testbeds for the robotics community such as the New England Robotics Validation and Experimentation (**NERVE**) Center at the University of Massachusetts Lowell, and the facilities at the Southwest Research Institute (**SWRI**) in San Antonio, Texas, incorporate both general test courses for robots and the **NIST** standard methods.

Perhaps the most influential physical simulation for researchers is the RoboCup rescue physical league which uses the **NIST** standard test bed for search and rescue, shown in Fig. 60.18. This competition started in 2001 [60.92] and has more than 40 team entries every year from all over the world. The RoboCup rescue physical league scores robot performance in terms of mobility, mapping, situation awareness, sensing, shared autonomy, etc. A robot or robot team competes in one

of three arenas which simulate disaster situations at the annual RoboCup world competition. The mission of the robot teams is to collect victim information (existence, state, and location) by sensor fusion of vital signals (heat, shape, color, motion, sound, CO₂, etc.) and report a map of victims in disaster space so that responders can efficiently arrive at the victim for rescue. In addition to the arenas, the competition and test bed contain individual skill test stations, for example, in order to test mobility, robots must traverse a random step field made of wood. The test bed was designed to be portable and reasonably inexpensive and several locations around the world have set up duplicates. As a result of the constraints of cost and portability, the test bed is not fully representative of actual disaster physical conditions and does not test the operating conditions for the human teams.

60.6.3 Standards Activity

Standards for rescue robots and systems are being generated at the time of writing. The E54.08 subcommittee on operational equipment within the E54 Homeland Security application committee of ASTM International started developing an urban search and rescue (USAR) robot performance standard with the National Institute of Standards and Technology (NIST) as a US Department of Homeland Security (DHS) program from 2005 to 2010. It plans to cover sensing, mobility, navigation, planning, integration, and operator control in order to ensure that the robots can meet operational requirements under the extreme conditions of rescue. The standards will consist of performance measures that encompass basic functionality, adequacy and appropriateness for the task, interoperability, efficiency, and sustainability. The components of the robot systems include platforms, sensors, operator interfaces, software, computational models and analyses, communication, and information. Development of requirements, guide-

lines, performance metrics, test methods, certification, reassessment, and training procedures is planned.

60.6.4 Evaluation

Evaluation of rescue robots is difficult not only because of the diversity of platforms and missions but also because each disaster is truly different. In addition, robots are part of a human-centric system: they are operated by humans in order to provide information to humans. Evaluation of the performance of a rescue robot system at an actual disaster is currently ad hoc. No computer or physical simulation for predicting the performance of robots and humans in a disaster has been validated; indeed, there is little argument that simulations are far easier than a real response. The difficulties of simulation are exacerbated by the differences between disasters. For example, the World Trade Center was unique in terms of the large amount of steel and the density of the collapsed material, while earthquakes and hurricanes are different from terrorist events.

Metrics for measuring performance remain a worthwhile quest. Quantitative metrics, such as the number of survivors or remains found, do not capture the value of a robot in establishing that there are no survivors in a particular area. Performance metrics from psychology and industrial engineering are only now beginning to be applied. These methods require enhanced computer and full-scale simulations in order to collect data. Data collection on human and overall system performance during a disaster has been done through ethnographic observations and are now moving to direct observations of situation awareness during demonstrations [60.80, 93]. Direct data collection during a disaster may not be possible as methods may interfere with performance (and therefore be unreasonable, if not unethical) and arouse fears by operators of *Big Brother* and being held liable for any errors in operation.

60.7 Conclusions and Further Reading

Rescue robots are making the transition from an interesting idea to an integral part of emergency response. Aerial and ground robots have captured most of the attention, especially for disaster response, but water-based vehicles (both surface and underwater) are proving useful as well. Rescue robots present challenges in all major subsystems (mobility, communications, control, sensors, and power) as well as in human-robot interaction. In terms of size, man-portable and man-packable systems are the most pop-

ular because of their reduced logistics burden, but the size of the platforms exacerbates the need for miniaturized sensors and processors. Wireless communications remains a major problem. While recent deployments have relied on polymorphic tracked vehicles, researchers are investigating miniature planes and helicopters along with new ground robots designs, particularly biomimetic. Research is also exploring alternative concepts of operations and user interfaces. Standards are currently under development and this

will help accelerate the adoption of rescue robots. The annual IEEE (Institute of Electrical and Electronics Engineers) International Symposium on Safety, Security

and Rescue Robotics is currently the primary conference and clearinghouse for research in rescue robotics.

61. Robot Surveillance and Security

Wendell H. Chun, Nikolaos Papanikolopoulos

This chapter introduces the foundation for surveillance and security robots for multiple military and civilian applications. The key environmental domains are mobile robots for ground, aerial, surface water, and underwater applications. Surveillance literally means *to watch from above*, while surveillance robots are used to monitor the behavior, activities, and other changing information that are gathered for the general purpose of managing, directing, or protecting one's assets or position. In a practical sense, the term surveillance is taken to mean *the act of observation from a distance*, and security robots are commonly used to protect and safeguard a location, some valuable assets, or personal against danger, damage, loss, and crime. Surveillance is a proactive operation, while security robots are a defensive operation. The construction of each type of robot is similar in nature with a mobility component, sensor payload, communication system, and an operator control station.

After introducing the major robot components, this chapter focuses on the various applications. More specifically, Sect. 61.3 discusses the enabling technologies of mobile robot navigation, various payload sensors used for surveillance or security applications, target detection and tracking algorithms, and the operator's robot control console for human-machine interface (HMI). Section 61.4 presents selected research activities relevant to

surveillance and security, including automatic data processing of the payload sensors, automatic monitoring of human activities, facial recognition, and collaborative automatic target recognition (ATR). Finally, Sect. 61.5 discusses future directions in robot surveillance and security, giving some conclusions and followed by references.

61.1 Overview

Surveillance robots and Security robots are tactically similar in design, but their specific purposes are very different. The surveillance robot uses its payload to map or search an area, while the security robot is used to protect and safeguard an asset such as the prime-

ter of an airport. In comparing these two categories of robots, the difference in operations would be analogous to comparing surveillance to a global problem and security to a local problem. Operationally, the surveillance robot collects data with its electronic payload

Fig. 61.1a–d Examples of surveillance and security robots. (a) Aerial-General Atomics Predator, (b) ground-QinetiQ TALON, (c) ground-General Dynamics MDARS-E, and (d) surface water-Elbit Stingray

(also known as the robot's external sensor) and relays the raw data back to its control station or preprocesses the data with other information such as geographic information system (GIS) data and relays that information to an exploitation element. Eventually as more autonomy is integrated into the vehicle, the robot will be able to plan its own paths and point its sensor with minimal human intervention. The quality of surveillance is a function of target range, the amount of target clutter, sensor resolution, and its probability of detection of a target. Security robot operations consist of a mobile robot patrolling a defined area (or perimeter), detecting an intruder or suspicious activities, and initiating a response. A security robot can conduct predefined or random patrols, and automatically perform surveillance tasks such as checking for intruders or assessing the status of the perimeter defenses. Input from the operator is required only if an intruder is detected or the robot encounters a situation it is not programmed to handle. Once contact is made, the operator is able to see, hear, and talk to the intruder. If the intruder tries to avoid the robot, the intruder can track them with its onboard sensor and maneuver the robot to follow the suspected intruder. Search and Rescue Robotics (Chap. 58) uses some aspects of surveillance due to the potentially wide area to be searched and the actions of security where upon detection, an action is required.

The basic security robot [61.1] can be as simple as a fixed-sensor, mounted up high and able to pan and tilt without being able to move around. There are concepts to use a low-cost sensor (to sense motion,

detect vibration, or break a sensor-beam) in order to cue a more sophisticated second sensor (e.g., radar or video) for confirmation. Depending on the complexity of the security system, the fixed sensor can alert a mobile robot, which can otherwise be defeated by just waiting for the robot to pass. A combination of fixed and mobile assets can be a very robust solution system. Again, the nominal robot configurations are still similar (Fig. 61.1): robot with sensor payload, an operator station, and a communication system that links the robot with its control station [61.2–5]. In some cases, there may be two distinct control stations, one for controlling the robot and one for handling the payload data as seen on military drones. A surveillance robot can be more data intensive as compared to the security robot which often performs in a structured environment and has a narrower data load to process. Central to both applications are the robot or robots, and the control station. Robot surveillance is in greater use today due to the war in the Middle East (Iraq and Afghanistan) with the proliferation of military drones. The majority of unmanned aerial vehicles (UAVs) are controlled via teleoperation or by flying automatically through waypoints. UAVs are now commonplace in the military, and slowly making inroads into the commercial sector with applications in agriculture, forest fire mapping, and weather analysis. The next technological step forward for surveillance robots is autonomous operations and multi-vehicle coordination (i. e., swarming). Robot security is less developed with some on-going research programs within the military, and a few commercial options available on the market today. Early mobile robot companies in the 1980s were formed to address these same security concerns such as Cybermotion Inc. and Denning Mobile Robotics, Inc. but did not survive over time. The next logical progression for robot security is to bring the costs down to make the systems more viable, reduce false-positives to make detection reliable, and take unnecessary personnel out of daily control through the careful insertion of automatic and autonomous technologies.

There are some fundamental issues that need to be addressed in the design and development of the surveillance or security robot system. For example, each specific applications will dictate if surveillance occurs indoors or outdoors, and similarly for indoor or outdoor security, such that sensors are different to address weather or lighting concerns. There are numerous applications for either case, and will impact the type of mobility chosen, and the type of sensors used for monitoring and detection. As noted earlier, robot surveillance typically requires mobility; while security robots can be either stationary or mobile. In the later, the environment is known (or classified as being struc-

tured) with set vehicle trajectories defined a priori in the majority of applications. Some robot security applications may involve a combination of both fixed and mobile robots depending on the size of the facility or building. The first issue to contend with is having to select between teleoperated and autonomous control of the robot. There is a scenario to start with a teleoper-

ated system that can eventually evolve toward a more capable automatic or autonomous capability. However, experience has shown that this upgrade seldom occurs naturally without planning and when the capability does mature, it will require large software block upgrades and the hardware will normally require upgrading also to increase overall capability.

61.2 Application Domains

Surveillance and security robot designs begin by first understanding its intended operational environment, and simultaneously designing for data collection or various protection schemas. The typical surveillance robot requires a surveillance payload, while a security robot integrates a security sensor. This sensor suite is in addition to a navigation sensor suite required by the robot for mobility. There may be an opportunity to use the same sensor for both navigation and payload, but this option is very isolated due to disparate range and resolution requirements. Since there are two different sensors, some coordination is required between mobility of the robot and the desired viewing angle of the payload sensor.

Surveillance and security robots (Fig. 61.2) can be found in all the normal environments (e.g., aerial, ground, surface water, underwater, or space), for example by watching from above from either space or from an aerial elevation. Robots patrols are found in ground [61.6, 7] and aerial applications:

- **Aerial Domain:** The majority of long distance aerial applications utilize fixed wing vehicles flying at a set altitude and monitoring large surface areas. Aerial vehicles come in all sizes from full-size platforms that are the size of passenger jetliners to small quad-rotors, vertical take-off and landing vehicles, and microflapping wing aircraft as described in Chap. 50. Electro-optical (EO), infrared (IR), or synthetic aperture radar (SAR) are sensors nominally used to collect surveillance data. A fixed-wing aircraft can also be used for security, but rotorcraft platforms (especially a quad-rotor) are the mobility of choice for its hovering capability as shown in  VIDEO 554. The weakness in rotorcraft platforms is its weight limitations, e.g., sensor payload weight and vehicle flight time. Key aerial design constraints are Reynolds number, Lift-to-drag (L/D) ratio of the wings, Breguet range analysis, vehicle endurance, and vehicle aspect-ratios. Communications between aircraft and ground control station is direct line-of-sight or over-the-horizon using satellites or other

UAVs when functioning as a communication repeater.

- **Ground Domain:** Ground vehicles are either custom-designed or based on retro-fitting an existing commercial or military vehicle. They come in all sizes from automobile-size to desk-size and shoebox-size such as the Dragon Runner as described in Chap. 48 and potentially walking as described in Chap. 65. An EO, IR, or range finder is used to collect surveillance data. For robot security, a similar EO, IR, lidar, or range finder sensors are often used as can be seen in  VIDEO 677. Key ground design constraints are types of vehicle steering modes, type of propulsion (wheeled, track, legged, or hybrid) system, range, suspension, and draw-bar pull performance. The standard packet-radio used for communications is bandwidth limited, thus ground robots would benefit from and automatic RSTA capability (RSTA: reconnaissance, surveillance, and target acquisition).
- **Surface Water Domain:** Surface vehicles are either custom-designed, or based on retro-fitting an existing boat such as a rigid hull inflatable boat (RHIB). They vary in sizes from a small jet ski to an 11 m RHIB. Surface water robots used for surveillance and security are in its infancy. Potentially, a radar can be used to conduct surveillance, data and for robot security, a combination of radar and EO sensors are envisioned. Key surface water design constraints are vehicle speed, range, and draft and beam dimensions for flotation. Surface navigation requires GPS for localization when visual techniques are ineffective and when water features are indistinguishable.
- **Underwater Domain:** Unmanned underwater vehicles (UUVs) vary in size from man-portable lightweight platforms to large diameter vehicles of over 10 m in length. The larger vehicles have an advantage in terms of endurance and sensor payload weight capacity as described in Chap. 51. Sonar is the payload sensor (sidescan or other) and is used to collect surveillance and support navigation data.

Fig.61.2a–e Wide ranging operational environments: (a) Air-Tacocopter, (b) Ground-Asian Forum for Corrections' Robo-Guard, (c) Underwater-Bluefin 9, (d) Surface water-Rafael Protector, and (e) Space-Ball Aerospace SBSS Satellite (SBSS: space based space surveillance)

The majority of operational **UUV**s are tethered, but untethered vehicles have a larger presence in the research world (better known as autonomous underwater vehicles or **AUV**s). Key underwater design constraints are Reynolds Number, buoyancy, endurance, pressure, and being tethered or untethered. Secure underwater communications is an issue for connecting the robot with its operators.

- **Space Domain:** Spacecraft by nature are considered robotic. There is a combination of onboard automation and a mix of commanding from the ground during critical events. Surveillance spacecraft range in size from microsatellites (50–100 kg) to traditional (approximately 15 000 kg) surveillance-size spacecraft, and the typical payload sensors include high-definition cameras and **SAR**. Security satellites are used to protect assets on the ground, and having the ability to detect and track objects from space is crucial to preventing threats, whether real or accidental.

Key spacecraft design constraints are weight, power usage, thermal cycling, surviving launch loads, and operating at cryogenic temperatures.

As shown, there is a wide range of surveillance and security robots in multiple domains. Domains have specific individual environmental concerns. A domain not discussed is underground, as experienced with mining applications or the surveillance of caves with the iRobot 110 FirstLook or other small unmanned ground vehicle. It is clear with all of these robots that there is a navigational component and a payload/sensor component. Coordination between navigating and sensing for surveillance and security is of interest to robotic researchers. As noted earlier, the dominant robot applications are aerial surveillance, which covers large surface areas by a fast moving aircraft, and ground (and surface water) vehicles for security that move slower on predefined paths.

61.3 Enabling Technologies

Robot surveillance and Security requires sensing, data collection, mobility (optional), navigation, communication, control, computer vision, and having a preplanned response (i.e., using deterrence) as a security action. Acceptable responses can be as benign as alerting a human guard, to immobilizing the threat, or potentially incorporating a weapon to remove the threat. There are many relevant technologies needed for this application. In this section, we will discuss the selected enabling technologies of: mobile navigation, payload sensors, applicable algorithms, and the human–robot interface at the operator control console.

61.3.1 Mobile Navigation

Teleoperated mobility is a well-developed technology as long as the communication bandwidth is available between the assets. For fast moving surveillance robots such as large aerial platforms [61.8], teleoperation is an

option but today's technology is to fly via **GPS** waypoints. Waypoints are sets of coordinates that identify a point in physical space such as *X*, *Y*, *Z*, or longitude, latitude, and altitude. Navigation systems such as **GPS** (or other radio triangulation systems, i.e., Loran or Kaman) are used to maneuver the aircraft to fly-over or fly-by the waypoints. Fly-by waypoints are used when an aircraft should begin a turn to its next course prior to reaching the waypoint separating the two route segments, and fly-over waypoints are used when the aircraft must fly over the point prior and start its turn. In practice, the aerial robot will fly directly overhead of a fly-over waypoint, and can miss a fly-by waypoint by a couple of miles due to a practice called *cutting the corner*. The critical phases for all **UAV**s are during its launch and at its recovery, and would benefit from emerging sense-and-avoid technologies. For underwater applications where **GPS** is not accessible unless the platform surfaces periodically, the robot [61.9] navi-

Fig. 61.4a,b Typical EO sensors: (a) UAV EO gimbal sensor suite (courtesy of forward looking infrared (FLIR) systems) and (b) (UGV) EO/IR gimbal sensor suite (courtesy of L3 – Wescam)

gates through the use of dead reckoning with frequent landmark corrections.

For unknown and unstructured environments, teleoperation for security robots is the state of practice for aerial, ground, and surface water applications. When there is a setup period and the path is known a priori, as within a *structured* environment, preplanned paths can be incorporated. For a more advanced ground robot, autonomous navigation [61.10] is being researched and developed (predominantly in the outdoor environment). Benchmarks for autonomous navigation (Fig. 61.3) in complex, outdoor environments were established on the DARPA PerceptOR and LAGR programs (LAGR: learning applied to ground robots; PerceptOR: perceptions for off-road robotics). Refer to Chap. 35 for techniques that contribute to an autonomous navigation capability.

61.3.2 Payload Sensors

The end-user for surveillance data are the commanders, decision makers, analysts, targeteers, weaponers (when a response is separate from the UAV), and

cartographers. The information sought is timeliness, synoptic coverage, sensor resolution, sensor accuracy, interior details, and the differing elevations. Some basic payload definitions are:

- Real-time: information arrives after the event at the speed of electrons.
- Near Real-time: information arrives between real time and 20 min after the event.
- Accuracy: level of agreement with standard map datum.
- Precision: fineness of resolution to which measurements can be made.
- Field of View: angular area observed by a fixed (nonscanning) sensor.
- Field of Regard: angular area observed by a scanning sensor.

Surveillance sensor options include passive imaging [61.11], active imaging, and nonimaging sensors. Film and EO sensors are passive imaging. An example of passive imaging on the DARPA UGV Demo II program is shown in [VIDEO 679](#). In addition to EO, IR optical sensors often accompany its daylight counterpart in order to be also able to see in darkness (commonly denoted as EO/IR). Active imaging sensors include radar and laser, while nonimaging sensors are SIGINT, MASINT, and chemical/biological. Passive imaging sensors are compared in Table 61.1.

There are many active imaging sensors (Fig. 61.4) such as SAR, a radar that uses its forward motion to synthesize the equivalent of a large side-looking antenna to produce high-resolution ground mapping. Moving Target Indicator (MTI) is a radar mode that uses differences in Doppler frequency due to the target's motion to distinguish it from stationary backgrounds (i.e., ground clutter). MTI has a wide field of view. Foliage penetration is radar using VHF/UHF frequencies and complex algorithms optimized to detect targets through foliage (VHF: very high frequency; UHF: ultra high frequency). Trees and leaves cover a good portion of the world's terrain. Inverse SAR is a radar mode using a target's angular movement (instead of using the platforms as for SAR) to detect moving objects, and Interferometric SAR is a radar technique using widely separated receivers to receive the same signal and combining them to produce three-dimensional (3-D) maps with highly accurate terrain relief. High resolution radar is radar using short wavelengths (millimeter wave) and sophisticated algorithms to produce high resolution (i.e., measured in inches) imagery. Laser imaging radar is a radar using light (laser), rather than radio frequency (RF) energy, for its illumination source. Robot researchers recognize LIDAR to refer to the acronym *Light Detection and Ranging*, and typically used in

Table 61.1 Passive imaging sensors

Sensor	Advantages	Disadvantages
Film	Best resolution Easily archived	Processing time compromises availability Dissemination copies degrade with reproduction
Electro-optical (visible)	Easy to data link while in-flight High resolution Easy to interpret (literal presentation) High fidelity reproduction	Cannot penetrate inclement weather Volume of data produced (current big data problem)
Infrared (cooled)	Provides imagery during the dark Penetrates some weather or obscurants Detects targets otherwise invisible due to range or background Provides evidence of recently past activity (IR traces), current activity level (engines running), or status (fuel tank levels)	Effectiveness diminished in warmer seasons, desert locales, hotter hours of the day, in Sun’s direction Resolution typically 1 NIIRs poorer than that of visible
Infrared (uncooled)	Same operational advantages of cooled IR sensors, but: More compact packaging Reduced power requirements Increased reliability Lower costs	Less sensitive to thermal differences Larger pixel size = less resolution
Spectral	Provides additional operational information about targets—counter CC&D (camouflage, concealment, and deception) techniques	Bandwidth intensive for data relay

Table 61.2 Active imaging sensors

Sensor	Advantages	Disadvantages
Synthetic aperture radar (SAR)	Sees at greater distances than visible Sees through (most) weather and night Provides constant perspective imagery	Power and processing intensive Large aperture
Moving target indicator (MTI)	Detects and tracks moving air/ground objects Builds history of traffic flow over set intervals	A SAR-dependent technique requires further processing of SAR returns
Foliage penetration (FOPEN)	Defeats most uses of foliage as camouflage Provides limited ground penetration capability	Resolution limited due to frequencies used
Inverse SAR (ISAR)	Detects small objects on moving backgrounds Examples: boats, periscopes, and icebergs	Performance varies with aspect angle
Interferometric SAR (IFSAR)	Achieves locational accuracies of 5–30 m Maps large amounts of terrain in a short time	Requires relative positions of receivers be known and maintained precisely Requires extensive post-processing of data
High resolution radar (HRR)	Range limited by frequencies used	Susceptible to intervening weather
Laser imaging radar (LIDAR)	Useful for bathymetry, pollution monitoring, and altimetry Potential for 2-D range-gated and 3-D imaging	Limited in range and by intervening weather

robot navigation. Active imaging sensors are compared in Table 61.2.

Examples of Nonimaging sensors are SIGINT, MASINT, and chemical/biological. SIGINT stands for Signals Intelligence. Electronic signals are passive and the emissions of electronic systems (from radars, navigational aids, and others) can be intercepted and interpreted. The challenge with SIGNIT is frequency hopping and spread spectrum. Another facet of SIGNIT is the interception of spoken communications signals (through radios, etc.). The common challenges with communication signals are digitization, encoding, enciphering, and/or frequency hopping. Measurement and Signatures Intelligence (MASINT) can be either ac-

tive or passive. MASINT adds additional dimensions to target data, but requires the intelligent interpretation of this data. Finally, chemical/biological agent sensors can also be passive or active. There are two types of chemical/biological (Chem/bio) sensors: point and remote, and these types of sensors perform based on air sampling and can detect when previous chemical or biological weapons have been used. Thus, Robots have many options for payloads, dominated by weight, power consumption, and field of view. EO/IR are the most commonly used sensors for surveillance. Its selection is based on resolution, optical efficiency, and detector responsiveness. Its resolution is a function of its detector array size and the field-of-view of the lens

used. Figure 61.5 is used to determine the desired resolution. Optical efficiency is dependent on lens diameter, lens focal length, and pitch. Finally, detector responsiveness is based on the detector's material, wavelength, and temperature. These are all physical parameters. A figure of merit used for a better payload is the product of its normalized resolution with a normalized optical efficiency with normalized detector responsiveness coefficient.

In summary, both **EO** and **SAR** sensors are approaching their limits of *immutable laws of physics*. The challenge today is in data reduction and its exploitation in support of surveillance. As a rule of thumb, surveillance sensors are selected based on:

- **VHF/UHF SAR** is used for foliage penetration and large area coverage.
- Microwave **SAR** for high resolution imaging from standoff ranges.
- Microwave ground moving target indicator (**GMTI**) radars for detecting moving targets and large area coverage.
- Electric support measures (**ESM**), **SIGINT**, and communications intelligence (**COMINT**) for intercepting, locating, recording, and analyzing radiated electromagnetic signals.
- Film for high resolution target classification/identification.
- **EO/IR** for targeting and target classification/identification.

A similar security payload also incorporates **EO/IR** sensors, but with resolution that commensurate with its shorter range to targets. As a rule of thumb, security sensors are selected as:

- Radar is used to detect moving targets at a long range.
- Radar for close-in target tracking.
- **EO/IR** for close-in target tracking.

Surveillance data is either stored for later use, or transmitted to exploitation centers for processing. Security data can be processed onboard the robot or transmitted to the operator control console for real-time observance or for limited post-processing. The key for security is in its algorithms with respect to detecting, identifying, and tracking a potential target or suspicious activities. If weight and processing power is not an issue, multiple overlapping sensors are used on robots to reduce false detections and confirm target identification [61.12]. This is a layered approach. Performance is increased when a wide area surveillance system is used for initial detection or cross-cueing. For example, an

Fig. 61.5 Determining sensor resolution for **ATR** or **RSTA** (courtesy of L. Newcome)

MTI sensor can provide a wide area search and collect coarse information about potential targets sufficient to cue the narrow field of view **EO** and **IR** sensors that can continue the process of tracking, classifying, and identifying potential targets. Payload sensors collect data, but it is the processing of the data into information that can be used by others that is the nugget for both the surveillance and security communities.

61.3.3 Detection and Tracking Algorithms

An important technology in surveillance reconnaissance, surveillance, and target acquisition (**RSTA**). This topic is also closely associated with intelligence, surveillance, and reconnaissance (**ISR**) and automatic target recognition (**ATR**). **ATR**, **RSTA**, and **ISR** are age-old problems in the military to identify and classify activities of interest in the environment [61.13–16]. During surveillance, the user has an option to acquire a target at a specified location, search an area or sector for either stationary or moving targets, perform a panoramic reconnaissance of an area or sector, initiate fire control, or manually control its sensors by a human operator to acquire surveillance imagery as depicted in Fig. 61.6. For example, if the sensor is stationary and the target is stationary, than a maximum-average-correlation-height approach where a bank of linear correlation filters are optimized to respond to the presence of a specific target object by producing a peak at its corresponding location can be very effective. If a stationary target search is used, the platform is directed to search a specified area for targets using stationary target detection and recognition algorithms.

Fig. 61.6 UAV sensor coverage with aircraft trajectory (courtesy of University of Illinois – Urbana Champaign)

These algorithms can detect both stationary and moving targets, but moving target detection does not make use of motion related information that is associated with a robot. Moving objects in the scene are the subjects of interest in most visual surveillance applications using **EO/IR** sensors. Specifically, the actions of the moving objects need to be monitored and appropriate flags need to be raised when events of interest occur in the scene. The mobile platform needs to be controlled so as to aid the surveillance task. Thus, the objectives of the surveillance task and the associated real-time computation constraints involve difficult challenges in building highly robust yet computationally cheap algorithms for detection, classification, and correspondence.

Manually, the user can select several options including the type of search modes to be used in which the sensor is assumed to be either stationary or moving, and the target is assumed to be either stationary or moving. For example, a **UAV** and satellite are always in motion, while the **UGV/USV/UUV** can either be either stationary or mobile. The selection of the stationary target mode causes stationary target detection and recognition algorithms to run, while the selection of the moving target mode causes moving target detection and tracking algorithms to be executed. The user would benefit from an automatic selection feature. The demanding nature of the required detection criteria for surveillance and security necessitates the integration of complementary technologies which can sense motion, characterize patterns, find thermal signatures, and capture temporal behavior as can be seen in **VIDEO 678**.

The **RSTA** or **ATR** algorithm sequence [61.17] include reconnaissance, acquire target through search, and finally target tracking. A panoramic reconnaissance command can direct the robot's payload to collect a mosaic of images over a wide field of regard and send it to the operator for manual viewing. There are several techniques used to create an image mosaic from a se-

quence of images. The registration between images is obtained by minimizing the sum-squared error of image intensities at each pixel. Although this technique produces very accurate registration results, it tends to be slow, and typically require operator interaction to initialize the registration function. The collected mosaic may be used to assess trafficability, check out regions of interest such as roads and bridges, and manually look for enemy targets. To acquire targets, the vehicle is directed to look at a particular map location or in a particular direction, acquire an image, and perform stationary target detection on that image. An operator can select several search options in which the robot is assumed to be either stationary or moving, and the target is assumed to be stationary or moving. The search area determines whether to search a map region or an azimuth-elevation wedge. An azimuth may be specified relative to the world (map) or specified in vehicle coordinates. The selection of the stationary target function causes stationary target detection and recognition algorithms to run, while selection of a moving target mode causes moving target detection and tracking algorithms to be executed. The search mode determines whether to search an area in a single time or multiple times frames. An **EO/IR** sensor can use a combination of image processing algorithms. Probing-type algorithms include connected-component analysis or a blob analysis.

A large body of image processing algorithms has been developed to detect targets using techniques including histogram manipulation, convolution, morphology, over- and under-sampling, quantization, and spectral processing using Fourier transforms and discrete cosine transforms (**DCTs**). These algorithms tend to be computationally intensive [61.18, 19]. Other popular **ATR** algorithms include binary template matching, multispectral imaging, and wavelet transformation techniques. Of the many types of image enhancement algorithms, a spatial convolution kernel filtering tech-

nique produces the most dramatic results. A convolution kernel generates a new pixel value based on the relationship between the value of the pixel of interest, and the values of those that surround it. In convolution, two functions are overlaid and multiplied by one another. One of the functions is the video frame image and the other is a convolution kernel. [ATR](#) algorithms can be broadly described sequentially as: target detection, a segmentation function, feature evaluation, and classification. Target detection approaches can be either image-based or model-based.

If stationary target search is used, the platform is directed to search a specified area for targets using stationary target detection and recognition algorithms. These algorithms can detect targets using blob extraction and blob tracking algorithms. When a potential target is detected, images are sent to a target recognition algorithm for additional processing. Target recognition can be accomplished through the use of a *hashing* algorithm. Various target detections are passed to the hashing algorithm for labeling as one of several target types contained in a database or perception library. The hashing algorithm also produces an estimate of target pose and when the processing is complete, the results are sent to the operator for verification. Moving objects are typically detected using background subtraction. For this type of search, the platform is directed to look at a specified area for targets using a moving target detection algorithm based on temporal differencing. Most surveillance systems use background subtraction as an efficient means of motion detection with a stationary camera. Unfortunately, background subtraction techniques are not always robust under camera jitter, varying lighting conditions, and moving foliage. Techniques such as affine transformations are used for image stabilization. Problems of a periodic nature such as jitter and moving foliage induce multi-modal distribution of pixel intensity values. If the classification of the background environment can be calculated, then the background can be subtracted from the image to enable the use of motion detection and segmentation algorithms.

One popular method for background model generation is the incorporation of autoregressive ([AR](#)) or infinite impulse response ([IIR](#)) filters. A single [AR](#) or [IIR](#) filter is used for each pixel to estimate the dominant mode of the background. The [AR](#) filter estimates the center and width of the dominant mode of the background, and it is associated with each filter per pixel is a value that approximates the probability that the mode represented by the filter is seen by the pixel. When an intensity value is seen by the pixel falls within the mode of one of the pixel's filters and the associated probability is greater than a preset threshold, then

the pixel is declared as background. When a particular intensity value is not represented by any of the filters for that pixel, a new filter is added with an associated low probability value. When a filter matches intensity value, its probability rating is increased and the probabilities of the rest of the filters associated with that pixel are decreased. Thus, at each detection cycle, the filters corresponding to a pixel adapts to better fit the values of its background. This motion detection technique is enhanced by the use of feedback from higher-level algorithms such as a classifier and/or a correspondence algorithm. The classifier has the capability to reject spurious detections. This information can be used either to create a new filter for the pixel or to increase or decrease the probability threshold for detection. Information from its correspondence can be used to predict future locations of detections. This considerably improves the quality of segmentation. Another correlation-based tracker function can be added, which controls the payload pan/tilt gimbal to keep a detected target centered in the image. A harder problem is when the target is moving and the sensor is also moving.

For security robots, camera-based [EO/IR](#) sensors have long been used for security and observation purposes as depicted in [VIDEO 681](#). Surveillance cameras are typically fixed at known positions and have coverage of a circumscribed area defined by the fields-of-view of the cameras. Although some recent vision research has addressed autonomous surveillance, in most cases, humans perform the sensory processing. For an autonomous surveillance example, a vision system can provide the geometric shape of the target and its angular location relative to a radar sensor, while its onboard radar system can measure both the distance to the target and its relative velocity radial to the vehicle. The target's perceived geometric shape and distance are then used to calculate its cross-section for purposes of human target classification. The complementary mix of using multiple sensor (camera and radar) technologies allows for greater than 99% probability of detection with less than 1% nuisance alarm rate (also known as false-positives) for fielding a robust security system. This is a good example of cross-cueing. Camera control can be seen in [VIDEO 702](#). Once a target is detected, it is tracked in the center of the collective field-of-view in order to provide verification using successive vision and radar-based detections. A track file is maintained on each detected target to correlate size, distance, speed, and other parameters over an extended period of time. This time-based integration approach allows the system to significantly reject nuisance alarms while using extremely high gains during the detection process. The classification procedure in a security application maps

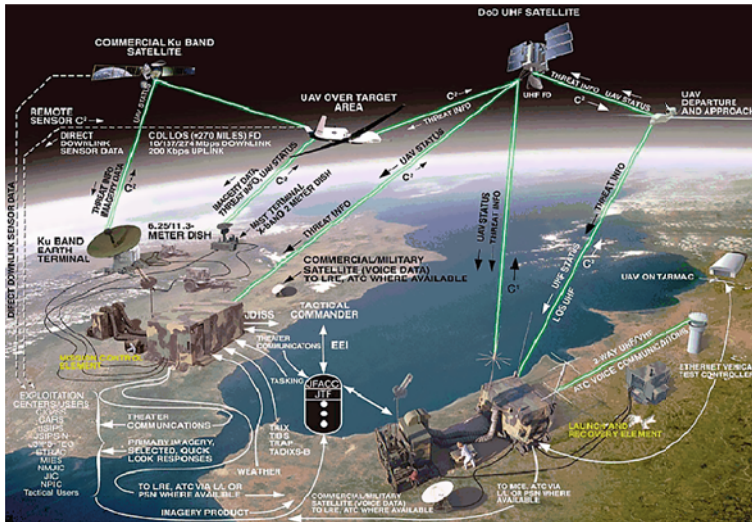

a given image sequence of a moving object to the most likely class label by classifying each image independently and then classifying the resulting set of class labels. The classifier can also reject classifying an object. For example, a classifier on the mobile detection assessment and response system (MDARS) program has demonstrated class-conditional sequence error rates of less than 5% and a false alarm rejection rate of 80% in disjoint testing. Unknown objects and novel views of known objects are detected by considering the class label history over an image sequence. Image sequences that yield a significant fraction of rejections or cause atypical classifier confusion are saved for later human interpretation.

In the last step, the temporal correspondence of a moving object plays a very important role in classifying, tracking, and interpreting an object's actions. Large number of targets of varying sizes in a scene preclude the use of simple positional correspondence, i. e., correspondence based purely on the positions of moving objects. In such situations, other features of the moving objects, such as different appearance traits, need to be considered for robust correspondence. For example, the measure of goodness of the features can be chosen not only on the object in question, but also on other objects in the scene. A globally *good* set of features can be estimated a priori, but only a subset of these features might be relevant to the correspondence of a particular object. Carnegie Mellon University (CMU) has developed a technique called *differential discriminative diagnosis* in which it provides a systematic method for estimating the relevance of features and checking the temporal consistency of these features for a particular object. The correspondence task is performed with a two-part process. The first part relies on positional correspondence using linear prediction. This part nominates a set of likely candidate matches for a reference object. The second part uses appearance-based correspondence to find the best match among those nominated by linear predictions. A simple linear classifier is trained based on learning techniques to determine whether or not two images are of the same object. Differential discriminative diagnosis identifies those features that are most relevant to the correspondence problem. Efficient correspondence is achieved by enforcing the temporal consistency of the *relevances* determined for a particular object, and this technique has demonstrated correspondence among moving objects with an accuracy of 96%. Target correspondence across multiple sensors can be achieved using a maximum a posteriori (MAP) estimate of the observation sequence to maximize target appearance and spatiotemporal probabilities. A correspondence problem is also used in stereo vision.

Another approach is to perform the correspondence step using a multiple robots configuration as in a swarm, which is addressed further in the multiple vehicle ATR active research area to follow (in Sect. 61.4.4). A more complex scenario involves multiple sensors detecting several targets simultaneously, and a moving sensor payload detecting a moving target [61.20, 21]. A moving target causes the radar signature to shift outside the normal return of a radar image. This shift in frequency (a Doppler shift) is used to distinguish stationary targets from moving targets. The detection of a moving target is more difficult when the sensor is also in motion. Augmenting data such as speed and heading of the moving target can be used to better *profile* potential targets. Other factors such as size, radar cross-section, and environmental clutter are used to make assumptions governing the type and intent of the target. MTI cross-cueing data has been overlaid in real-time on to 3-D visualization of the terrain to allow an operator to quickly locate a target such that the EO/IR sensor could be rapidly slewed to the target of interest. Test results have shown that wide field-of-view MTI radar that is used to cue a limited narrow field of view EO/IR sensor has drastically increased situational awareness on the battlefield. The next evolution is to automate the cross-cueing process in order to track, classify, and identify potential stationary and moving targets [61.22].

61.3.4 Human–Machine Interface

Unmanned aerial robots that are used for surveillance come in all types from the smaller, hand launched Raven, Puma, and Wasp drones to the mid-size Aerosonde and ScanEagle to the larger Predator, Reaper, and Global Hawk platforms that can stay airborne for 24 to greater than 28 h missions [61.23]. The Global Hawk architecture is depicted in Fig. 61.7 with its many communication links. The larger UAVs and their ground segment components interact through an over-the-horizon (OTH) satellite relay and line-of-sight (LOS) links to maintain command and control and sensor data dissemination communication paths for launch, flight, and recovery. Bandwidth compression is applied to the sensor data to maximize area coverage and data throughput. The communications systems are being designed to minimize susceptibility to jamming and interception. Dissemination of UAV collected intelligence is made through direct downlinks to national and theater intelligence centers and other exploitation systems, or through established *hard* communications between UAV ground control stations, and the exploitation systems. The UAV ground control station has limited capabilities to disseminate collected intelligence directly to an exploitation ground system

or battlefield customer. When deployed, a fully operational system consists of four Predators (with EO/IR sensors), a ground control station (GCS) that houses the pilots and sensor operators for human-machine interface (HMI), and a primary satellite-link communication suite.

The Predator UAV can run autonomously, executing simple missions such as reconnaissance on a software program, or it can run under the control of its crew (Fig. 61.8). The crew of a single Predator consists of one pilot and two sensor operators. The pilot drives the aircraft using a standard flight stick and associated controls that transmit commands over a C-Band line-of-sight data link. When operations are beyond the range of the C-Band link, a Ku-Band satellite link is used to relay commands and responses between a satellite and the aircraft. Onboard, the aircraft receives orders via an L-3 Communication satellite data link system. The pilots and crews use the images and radar received from the aircraft to make decisions about controlling the aircraft. The pilot's main mission is to fly the plane, while the sensor operator controls the cameras that bring the

battlefield into full view to gain intelligence. Unlike other manned missions, pilots for large UAVs only control the plane during landing and takeoff. However, sensor operators do much more than watch the feedback from their cameras [61,24]. Working together with pilots, they do preflight checks, coordinate with the air control tower, and provide feedback to pilots. The intelligence data is streamed back to exploitation elements where the data is analyzed by people on the ground or with automatic detection algorithms. Not including the exploitation element, it currently takes approximately 82 personnel to operate four of the larger UAVs for a 24 h period including technicians and support personnel.

Typically, unmanned ground robots used for security [61.25, 26] are available in limited options from the commercial Vigilus system, Reborg-Q security robot, OFRO (by Quadretec Ltd.) and patrolbot, to the army's mobile detection assessment and response system (MDARS) and its family of integrated rapid response equipment (FIRRE). The MDARS [61.27] system consists of ground robotic platforms capable of

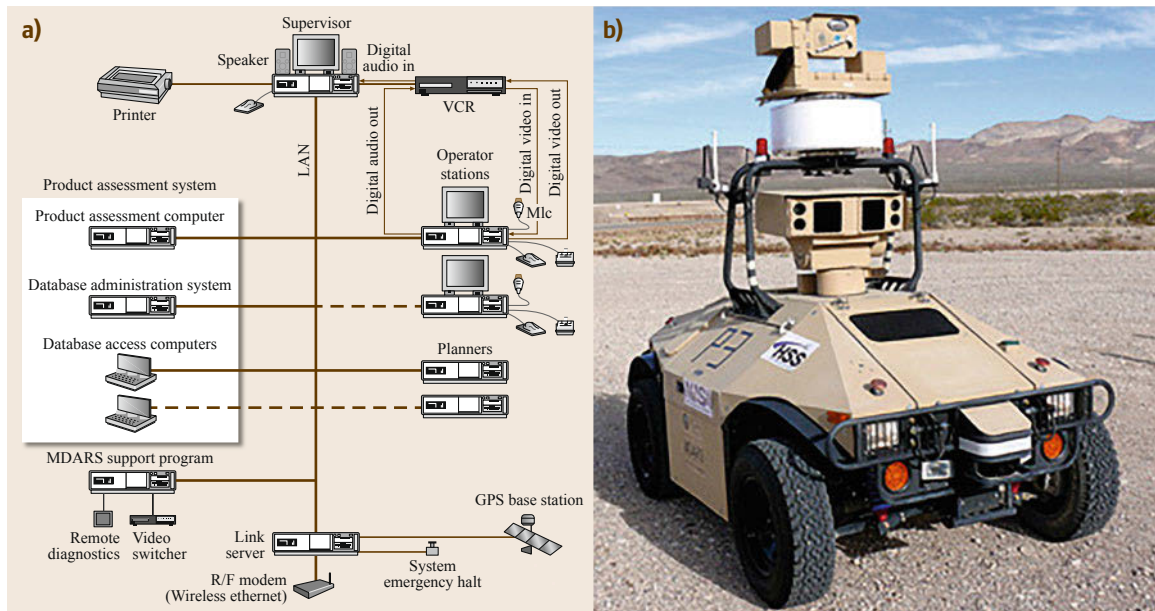

Fig. 61.9 MDARS operational concept and system components (courtesy of Space and Naval Warfare Systems Center (SPAWAR), Pacific)

preprogrammed autonomous movement, motion detection, an incident assessment subsystem, and two way communications capability between operator and robot. Its operational configuration will consist of pair(s) of mobile platforms employing a suite of sensors that are preprogrammed or remotely controlled by an operator located at a remote monitoring and control station. The actual number of fixed and mobile patrol units for a given location will be site specific. The MDARS Increment 1 system components are depicted in Fig. 61.9 with its various interfaces. All such robots and sensors (known collectively as resources) are controlled by the multiple resource host architecture (MRHA), with minimal human (i. e., security personnel and operators) supervision required [61.28]. The individual processors are connected via an Ethernet local area network (LAN) that supports a peer-to-peer communications protocol (expandable to 32 platforms or robots). The user interface provides a *big picture* representation of secured areas and system resources. User intervention is required only when a platform encounters an exceptional condition such as an environmental hazard or a security breach.

The operator control unit is either in monitor mode, in which the operator observes and monitors the status of the robot and sensors, or the operator is in direct control of a single resource such as a single robot in a multi-robot system. Moreover, the robot itself carries a number of sensory systems, each of which must also be controlled individually. For example, MDARS may

have eight cameras, two radars, and four lights, but only a single camera, radar, and light is controllable at any given time as shown in [VIDEO 680](#). Multiple cameras can be viewed simultaneously, but the operator cannot pan two of them at the same time. A joystick button or dialog button can be configured to cycle between the various payloads. The control of the resources and each of its selected subresources is integrated in such a way that a single joystick can be used to perform all relevant joystick tasks. As an example, the operator can pan the selected camera with the joystick, and then press a button to put the robot in teleoperation mode and drive the robot using the same joystick. The concept of modes is used to provide rich control features for each resource. This paradigm reduces the complexity of the software and simplifies the user interface presented on its displays, while still giving the operator full control of each asset. The MDARS control station allows the operator to execute preplanned patrols, random patrols, or user-directed patrols as seen in [VIDEO 701](#). Automation of sensor selection would improve operations.

The controller displays can perform basic image processing, which means they take in video at a certain resolution, and display it in the display's native resolution [61.29]. Video processing is the act of scaling, which is converting an incoming video signal from one size or resolution to another in order to work with the display panel. This is what is usually referred to as *video processing*, and it is a minor feat compared to video enhancement. Video enhancement techniques can

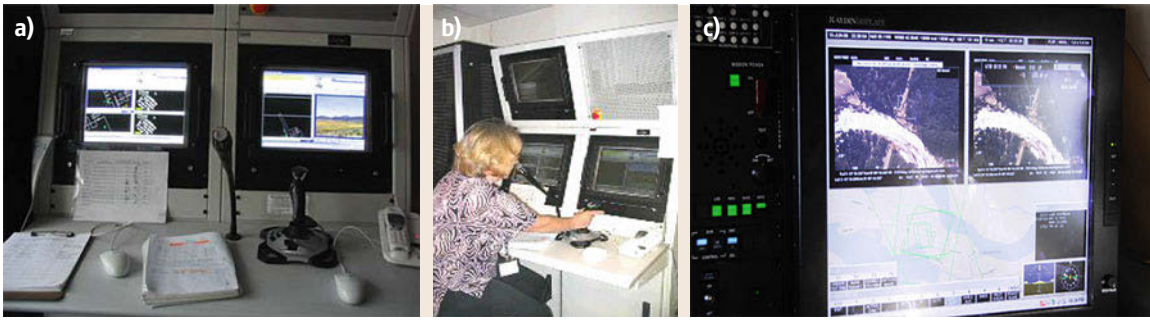

Fig. 61.10a–c MDARS mission control center. (a) Control station, (b) MDARS operator, and (c) display (courtesy of SPAWAR)

be based on spatial domain methods or frequency domain methods [61.30]. Image enhancement algorithms offer a wide variety of approaches for modifying images to achieve visually acceptable images. The choice of techniques implemented is a function of the specific task, image content, observer characteristics, and viewing conditions. Mosaic images provide better visualization of a tracking scenario. All security sensors are fused together to form a composite *threat score* on potential targets, and intruder alarms are reported to the user on the MDARS console (Fig. 61.10). Also, the intruder's range and bearing are displayed on a map

window and a digital stream from the camera is shown in a video window. For ATR, the operator receives notification of a target by the appearance of an icon on the map display at the operator interface. Selecting an icon brings up a target verification panel and a target response panel showing the imagery associated with the target that was provided by the sensors. With experience, most operators became comfortable and competent with normal operations, and each acquiring variable levels of proficiency in responding to exceptional events such as dealing with intruders or taking manual control of the robot.

61.4 Active Research

In addition to enabling robotic surveillance and security technologies, there are many active areas of robot research, such as being able to produce high-quality imagery from a mobile platform that poses a number of challenges. In addition to issues related to camera motion and the resulting image perspectives, the quality of the video imagery can also be compromised by poor environmental conditions, data link degradations,

and bandwidth limitations. Atmospheric factors such as poor lighting at dawn, dusk, or night time, the presence of shadows, target occlusion and adverse weather, including sandstorms and variable clouds, can obscure important details. Some identified areas of interest include: Sect. 61.4.1 in solving the data processing problem due to the large amounts of sensory information collected, Sect. 61.4.2 detecting human activity in

Fig. 61.11 Automatic target recognition (courtesy of Bilkent University)

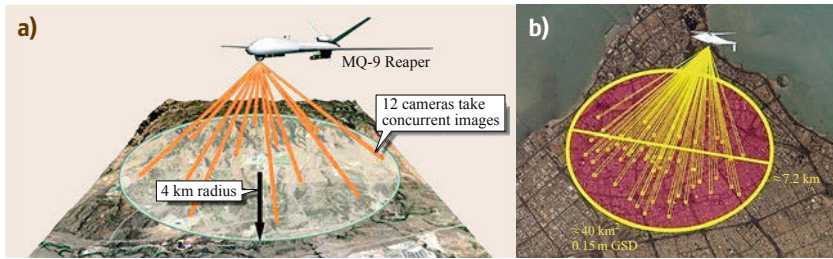

Fig. 61.12a,b Multiple real-time video stream sensors. (a) Gorgon Stare (courtesy of Sierra Nevada Corp) and (b) ARGUS-IS (courtesy of BAE Systems)

support of surveillance, Sect. 61.4.3 facial recognition for security identification purposes, and Sect. 61.4.4 collaborative *ATR* by multiple robot in either heterogeneous or homogeneous systems.

61.4.1 Solving the Data Processing Problem

With all the useful information that *UAV*s provide comes the problem of how to sort through it all and find actionable data. This is the *Big Data* problem for the military. One manual solution to the data explosion problem is to tag the data, store it, and retrieve it when needed. Unfortunately, this information would not be timely. Data fusion involves the use of techniques and software that combine data from multiple sources and analyze the data to make it useful for the end user [61.31]. Data fusion can involve the combining of data (such as *UAV* video) with a *GIS*, which adds location and time data to the images gathered (Fig. 61.11). To accomplish this, the raw data has to be combined with metadata, which is information about the data that enables the data to be combined. On-going research such as with *intelligent search* is another tool that can be used to make *UAV* data more accessible. Based on modern artificial intelligence (*AI*) techniques such as machine learning, depth first searches using iterative deepening, or depth first searches based on space complexity, users can quickly personalize a search to make relevant data more easily available [61.32].

To help users retrieve information, one promising method, called natural language processing, discovers user preferences and needs by either extracting knowledge from what users are looking for or by interactively generating explanatory requests to focus users on the information they are interested in [61.33]. The use of natural language to improve the performance of the intelligent search engines is one aspect of *AI*. Other related *AI* technologies for automated processing include object recognition and statistical machine learning, or application of *AI* in intelligent search is facial recognition. One promising solution that could help with the data overload issue is more efficient techniques for sensor fusion. For example, a multisensor fusion algorithm that can bring together

information from multiple platforms about a particular target of interest in a unified display would be beneficial to the operator. Researchers will need to develop smart technologies that automate the entire process of archiving, tagging, retrieving, managing, and displaying data and other information gathered by increasingly sophisticated sensors. As an adjacent topical area, machine-to-machine interfaces will need to become much more transparent in order to handle the data deluge [61.34].

A future technology called wide area surveillance (Fig. 61.12) is based on a new sensor system called Gorgon Stare, a video capture technology that uses a spherical array of nine to twelve cameras attached to an *UAV*. With so many sensors, Gorgon Stare needs to utilize a system of tagging and incorporating metadata to be fully effective. Initial reports on the progress of Gorgon Stare is that there are deficiencies in its *IR* performance, having numerous interoperability problems, having a lack of stability of the sensors, and encountering reliability problems. These issues can be overcome as the program matures. Unfortunately, the new sensor system is still limited by the human's inability to process the information gathered from many cameras, or rely on advanced automatic processing techniques to fuse the information into the coherent picture.

61.4.2 Detecting Human Activity in Support of Surveillance

The problem of using computer vision to track and understand the behavior of human beings is a very important tool for surveillance and security operations. At its highest level, this problem tries to recognize human behavior and understanding intent and motive from visual observations [61.35, 36], and [61.37]. This is a difficult task, even for humans to perform, and misinterpretations are common. The problem has several subareas of human motion recognition, surveillance, tracking, and activity detection. In the area of surveillance, automated systems to observe pedestrian traffic areas and detect dangerous action are becoming important. Many such areas currently have stationary surveillance cameras in place. However, all of the image understanding

Fig. 61.13 Monitoring individual and group human activities (courtesy of University of Minnesota)

and risk detection is left to human security personnel. This type of observation task is not well suited to humans, as it requires careful concentration over long periods of time. Therefore, there is clear motivation to develop automated, intelligent, vision-based monitoring systems that can aid a human user in the process of risk detection and analysis. Eventually, this capability will migrate from stationary cameras to mobile security applications.

Most of these human activity applications require an automated recognition of high-level activities, composed of multiple simple (or atomic) actions of persons as depicted in Fig 61.13. The goal of human activity recognition is to automatically analyze on-going activities from EO/IR sensors through a sequence of image frames [61.38]. There are various types of human activities and depending on their complexity, human activities can be categorized into four different levels based on: gestures, actions, interactions, and group activities. Gestures are elementary movements of a person's body part and actions, and is defined as single-person activities that may be composed of multiple gestures organized temporally. Interactions are human activities that involve two or more persons and/or objects as shown on VIDEO 683, while group activities are the activities performed by conceptual groups composed of multiple persons and/or objects. Promising events for activity monitoring include the detection of loitering individuals [61.39], and the detection of unusual crowd activities [61.40], which can be difficult to discern from normal crowd activities. It would be useful for security robots to detect motion in restricted areas [61.41], detect perimeter breaches, and detect when security cameras are tampered with [61.42]. Also of interest which may or may not involve the human include the throwing of an object or the detection of an abandoned object. The University of Minnesota has done

work in detecting abandoned objects as referred to in VIDEO 682.

There are several approaches used in the recognition of different levels of activities. Single-layered approaches are approaches that represent and recognize human activities directly based on sequences of images while hierarchical approaches represent high-level human activities by describing them in terms of other simpler activities. Single-layered approaches are divided into two classifications depending on how human activities are modeled directly from the video data: space-time approaches (a sequence of two-dimensional (2-D) images placed in chronological order) and sequential approaches (a sequence of observations). Unfortunately, the majority of activity monitoring algorithms is far from being real-time, which is an issue for surveillance. Robot surveillance is demanded in today's environment where the tracking and monitoring of people is an integral part of everyday activities. Monitoring is typically accomplished with multiple cameras [61.43] and from multiple vantage points. Activities of interest vary widely from throwing an object [61.44] to the subtle task of abandoning an object such as a backpack or leaving on unknown package [61.45]. In many instances, it would be important to estimate or count the size of a gathering [61.46–48]. Activity monitoring suffers from the same issues associated with ATR such as signed noise, tracking issues, and segmentation issues arising out of the stabilization of video images. There are a large number of new and promising improvement methods on the horizon, including space-time feature-based approaches, manifold learning, rigid/nonrigid motion analysis, and hierarchical approaches.

61.4.3 Facial Recognition for Security Identification

In order for a security robot to perform its mission to protect and safeguard, sometimes it will encounter people which have to be discerned as either friend or foe. In order to make such a determination, face recognition is critical [61.49]. Most of the current face recognition algorithms can be categorized into two groups: image template-based or geometry feature-based [61.50, 51]. The template-based methods computes the correlation between a face and one or more model templates to estimate the face's identity. For the other approach, the geometry feature-based methods analyze explicit local facial features, and their geometric relationships. Face recognition is a two-step procedure consisting of first detecting a face and followed by recognition. Top researchers have argued that the accurate detection of human faces in arbitrary scenes is the most impor-

Fig. 61.14 Local binary patterns using OpenCV (courtesy of Yale University)

tant process involved, followed by the face recognition process. When faces could be located exactly in any scene, the recognition step makes the final determination of classifying the person as being either friend or foe.

Algorithms are used to know how to differentiate between a basic face and the rest of the background. If the background is controlled (referred to as being highly structured and uncluttered), an algorithm to remove the background will produce face boundaries. Faces can be found by either using color, motion, or a mixture of both types of information. The detailed steps include acquisition, normalization, and recognition of moving faces in dynamic scenes. Color as a cue can be used for detection and tracking, and provides a computationally efficient yet effective method which is robust under rotations in depth and during partial occlusions. This method can be combined with both motion- and appearance-based face detection. The main idea is to model a class-conditional density for each person in a representation space of relatively low dimensionality. Unfortunately, color detection doesn't work on all kinds of skin color, and is still susceptible to varying lighting conditions.

Humans must periodically blink to keep their eyes moist, and detecting a blinking pattern in an image sequence is a reliable means of detecting the presence of a face. Blinking provides a space-time signal which is easily detected and unique to faces. Detection by blinking is precise, but requires capturing an image pair during a blink. A common technique for recognition is the correlation with a set of Eigen images. Better results have been demonstrated by combining stereo, color, and face detection techniques into an integrated approach [61.52]. Depth estimation using stereo cameras is used to eliminate background effects. Skin-hue classification identifies and tracks likely body parts within the silhouette of a user, while face pattern detection dis-

criminates and localizes the face within the identified body parts. Other approaches to finding faces include the use of neural networks, taking advantage of statistical cluster information, and model-based face tracking. Related work continues using edge-based methods and geometric models such as edge-orientation matching and using the Hausdorff distance measurement. The leading face finding algorithm in unstructured environments is based on a series of weak classifiers such as Haar-like features, representation by integral images, and a method for combining successively more complex classifiers in a cascading structure which can increase the speed of detection by focusing attention on promising regions of the image. An example of facial recognition can be seen in [VIDEO 553](#).

Upon detecting faces, facial recognition has numerous distinguishable landmarks, where different peaks and valleys make up facial features (Fig. 61.14). Measurements of these features include:

- Distance between the eyes
- Width of the nose
- Depth of the eye sockets
- The shape of the cheekbones
- The length of the jaw line.

The 2-D (or 3-D) image of the face is compared to a database of known people's faces. After detection, the image is analyzed to determine the head's position, size, and pose estimation. The sensor measures the curves of the face to a submillimeter scale to create a template. This face template is translated into a unique code that represents the features on the face. This is followed by a matching function that compares the image taken with a database of known faces. This is followed by a verification step that identifies the person in the image.

Skin biometrics can be used to verify the match. Techniques such as Surface Texture Analysis, Local Feature Analysis, and Vector Templating are used to improve the match. There are some impediments to facial recognition such as a lack of resolution in the sensor, glare from glasses, obscuration due to long hair hiding features of the face, and poor lighting conditions. The wider issue is to obtain and maintain an up-to-date database for matching. It would be simple to keep records on who belong to the facility, and to declare unknown faces as foes. However, there will be instances that the human is not a foe, but does not exist in the database either. Another issue would be a scenario in which there are multiple human intruders that stretches the capability of the robot security system. As a final verifier, the human operator can be used to make the final determination as friend or foe, visually or through an interrogation process.

Fig. 61.15 Collaborative ATR (courtesy of NATO)

61.4.4 Collaborative ATR

Swarm robots are a new approach to the coordination of multi-robot systems that consist of large numbers of robots, either homogeneous or possibly heterogeneous robots, i. e., team of air and ground platforms as depicted in  VIDEO 700. Swarming implies that a collective behavior emerges from the interactions between robots or the interactions of robots with its environment [61.53, 54], and [61.55]. In a coordinated team approach, individual platforms are able to pass target location information to one another during a target search operation in an attempt to get confirmation of a suspected target. Thus, a robot that detects a target passes the target's location (and a surrounding map-based uncertainty region) to another robot for confirmation. The confirming robot searches the nonoccluded portion of the given map region for the detected vehicle and returns the results of its search to the originating vehicle where they are compared with the original search results (Fig. 61.15). A final target's result is compiled and sent to the operator for verification.

The intent of cooperative target search is to increase the accuracy and reliability of the target search process. The conditions under which this search is guaranteed to be accurate must deal with the following issues:

- It is unclear under what conditions the originating vehicle can be sure that a positive response from the confirming vehicle corresponds to the same target or to any target at all.
- If the orientations of either or both robots are off significantly from their true orientations, it may be that the vehicles are not searching the same map region or that different targets within the uncertainty region are reported as the same target.
- Cooperative target searches puts stringent demands on the accuracy of vehicle orientation estimates. This problem can be partially alleviated by having

reliable, long-range laser rangefinders on all participating robots.

- Cooperative target search also puts stringent demands on the accuracy of target detection and recognition algorithms. For example, it is not unusual for an unsophisticated target detection algorithm to generate a positive return from a warm rock or large animal.
- The fact that the confirming vehicle may return a positive response does not increase the probability that the object is actually a valid target. In trials, confirmation of nontargets has actually been observed in field testing.
- It is also difficult to tell whether the confirmation of a valid target results from observation of the same target or detection of a false target. To alleviate this kind of problem, accurate and sophisticated target recognition algorithms are required.

Another concern is when the confirming robot returns a negative response. This lack of confirmation may indicate nothing more than that the confirming robot is looking in the wrong area or that it simply failed to detect a target that is present in its sensor's field-of-view. At this point, it is unclear under what conditions the originating vehicle should disregard its own initial detection. These issues provide motivation for researchers to develop more sophisticated ATR algorithms to obtain higher confidence reports and reduce the number of false alarms. These same issues also provide motivation for the development of context understanding algorithms.

Since cooperative target searches place these stringent demands on the accuracy of vehicle orientation estimates, teams of surveillance platforms must solve the multi-robot distributed estimation problem [61.56] and the related source localization problems [61.57]. Each of the robots collects sensor data regarding its own motion and shares this information with the rest of the team during periodic update cycles. A single estimator, possibly in the form of a Kalman filter, processes the available positioning information from all the members of the team and produces a pose estimate for every one of the robots. The equations for this centralized estimator can be written in a decentralized form, therefore allowing this single Kalman filter to be decomposed into a number of smaller communicating filters. Each of these filters processes sensor data collected by its host robot. The exchange of information between the individual filters is necessary only when two robots detect each other and measure their relative pose. The resulting decentralized estimation schema, which referred to as *collective localization*, constitutes a unique means for fusing mea-

surements collected from a variety of sensors with minimal communication and processing requirements. What complicates the estimation is that the robots are moving and the targets (or multiple targets) may also be moving.

Researchers have introduced a simple updating rule defining a distributed estimation scheme that balances consensus with tracking. It was shown that the probability distribution of the vector of estimates obeys a *Master Equation* derived from first and second moment dynamics. From this master equation, the evolution of its mean estimate and its variance can be computed. If the individual robots ignore the discrete state and simply do consensus, the estimates converge with the probability of *one* to the average of the initial values of the estimates. Moreover, by appropriately weighting the discrete state in the update rule, the average can be tracked with an arbitrarily small variance at steady state conditions.

Source localization is addressed by incorporating a visual gradient-based approach for a robot to adaptively search a location-unknown source. While mov-

ing, the robot only measures the received image quality and adaptively decides the motion direction in each time instant. Simulation results indicate that the robot can reach the sensor when the initial signal-to-noise ratio (SNR) is as low as 0 dB and the standard deviation of motion errors is 10% of the motion step size. Due to the adaptive nature of this solution, this approach is robust to measurement noise and motion errors. Since the robot moves along the direction of the gradient estimated at each time, the approach can be applied to an arbitrary signal strength distribution in an area [61.58]. One of the scenarios can be in an environment of obstacles so that the robot at the initial location does not have a line of sight to the sensor. The other scenario to consider is that the source is a cluster of activated sensors that send signals at the same time. Thus, the gradient approach can be extended from 2-D to 3-D space for applications incorporating aerial vehicles [61.59]. A multi-robot system can be applied to both the surveillance problem and the security scenario, but continued research is required to make such a system robust and practical.

61.5 Conclusion

Robots for surveillance typically involve unmanned aerial vehicles that can cover large areas and sit on regions of interest to provide a persistent presence [61.60]. UAVs today utilize teleoperation or flies via way-points on longer traverses to search selected regions. During flight, there are instances in the mission profile where launch and recovery operations are also autonomous. With EO/IR and SAR payloads, the data is streamed back to processing elements for post-processing. This becomes a bottleneck due to the high number of platforms in theater and the enormous volume of data that cannot be processed in real-time. These operations are also highly susceptible to weather issues, and impacted by delays and bandwidth limitation issues associated with the many communication links utilized. Collaborative ATR with swarms of vehicles is an emerging capability, but introduces its own set of issues in terms of consistently and correctly identifying targets of interest. Finally, there are related efforts in ground and unmanned surface water (USV) RSTA, and present different environmental-type challenges such as handling sensor motion issues due to buoyancy or flying indoors (see VIDEO 703).

Security robots are a maturing capability, but yet to be commonplace. The vision is to have a single operator commanding multiple stationary and mobile robots to deter criminal activities, especially the destructive

actions of some people. The overall mission is to detect, assess, and take action in order to deter a potential threat. Typical robots include ground platforms, hovering type vehicles, and surface water vehicles of all sizes. Key issues include the monitoring of human activities, detecting faces, and determining the extent of the potential threat. With multiple sensors available to

Fig. 61.16 Humanoid KUBO as a security guard (courtesy of Korea Advanced Institute of Science and Technology (KAIST))

the operators, there will be limited opportunities to confirm the target or set of targets due to time sensitivities. Moreover, sensor fusion can deliver a more complete picture of the situation for human or automatic confirmation. Affectivity of the system is quantifiable based on measuring coverage, having a high recognition rate, and demonstrating a low false alarm rate. A future direction is to potentially arm the security robots, but this introduces a new series of issues such as liability and ethics. Chapter 80 (Roboethics: Social and Ethical Implications) expands on these larger societal issues.

A future of humanoids (Fig. 61.16) and social robots used for surveillance and security is an inevitable possibility [61.61]. Humanoids (Chap. 67) provide bipedal mobility as a ground robot, and have an inherent

sensor payload with its head. However, the head sensors must be used to both navigate and perform reconnaissance. Its surveillance capability is limited by the field of view and resolution of its head cameras, but has expanded orientation capabilities based on its anthropomorphic neck and torso gimbals. This type of robot can take advantage of existing RSTA algorithms such as human activity monitoring, face recognition, and collaborative ATR for target confirmation as discussed previously. However, all these features are dependent on having adequate onboard processing capability in order to make real-time confirmation and decisions. Who is to say a future humanoid security robot cannot pick up a remote sensor suite similar to binoculars in order to search and detect a potential intruder?

62. Intelligent Vehicles

Alberto Broggi, Alex Zelinsky, Ümit Özgüner, Christian Laugier

This chapter describes the emerging robotics application field of intelligent vehicles – motor vehicles that have autonomous functions and capabilities. The chapter is organized as follows. Section 62.1 provides a motivation for why the development of intelligent vehicles is important, a brief history of the field, and the potential benefits of the technology. Section 62.2 describes the technologies that enable intelligent vehicles to sense vehicle, environment, and driver state, work with digital maps and satellite navigation, and communicate with intelligent transportation infrastructure. Section 62.3 describes the challenges and solutions associated with road scene understanding – a key capability for all intelligent vehicles. Section 62.4 describes advanced driver assistance systems, which use the robotics and sensing technologies described earlier to create new safety and convenience systems for motor vehicles, such as collision avoidance, lane keeping, and parking assistance. Section 62.5 describes driver monitoring technologies that are being developed to mitigate driver fatigue, inattention, and impairment. Section 62.6 describes fully autonomous intelligent vehicles systems that have been developed and deployed. The chapter is concluded in Sect. 62.7 with a discussion of future prospects, while Sect. 62.8 provides references to further reading and additional resources.

62.1 The Motivation and Approaches to Intelligent Vehicles

An important field of application of robotics has emerged in the last 20–25 years which is centered on the automobile, named *intelligent vehicles*. The automobile has been one of the most important products of the twentieth century. It has generated an enormous industry and has given individuals a freedom of movement that has completely changed our way of life. Indeed, the automobile has been a key factor in the large change in the way our urban societies are structured. Today, there are more than 800 million vehicles on the planet, and this number is expected to double in the next 10 years. This challenge has led to the development of an active research domain with the ultimate goal of automating the typical tasks that humans perform while driving. An intelligent vehicle is defined as a vehicle enhanced with perception, reasoning, and actuating devices that enable the automation of driving tasks such as safe lane following, obstacle avoidance, overtaking slower traffic, following the vehicle ahead, assessing and avoiding dangerous situations, and determining the route. The overall motivation for building intelligent vehicles has been to make motoring safer, and more convenient and efficient.

Approaches to this problem revolve about three main architectures [62.1], according to the degree of autonomy they aim for (Fig. 62.1):

- a) Driver-centric approaches are built around the idea of having a human in the loop supervising the functions of the vehicle.
- b) Network centric-approaches assume that vehicles can share information with other vehicles or the infrastructure.

- c) Vehicle-centric approaches aim to build fully autonomous intelligent vehicles with no human in the loop.

62.1.1 Brief History

Futurama was an exhibit at the 1939 World Fair designed by Norman Bel Geddes that presented a possible model of the world 20 years into the future (1959–1960) with automated highways. The exhibit was sponsored by the General Motors Corporation and was characterized by its vision of automated highways. Technological development in support of this vision began in the late 1940s and early 1950s, with pioneering efforts by RCA Laboratories and GM Research. By 1960, GM had tested full-scale cars driving automatically on test tracks, with lane tracking, lane changing and car following functions automated. The goal of these efforts was the development of an automated highway system (AHS). In the 1960s, a key effort was research and development under the leadership of Fenton and his team at The Ohio State University [62.2]. During these years, vehicles were developed to test steering and speed controllers. Runs were accomplished at the Transportation Research Center (TRC) grounds, using active sensing (a live wire imbedded in the roadway) and with steering control done with analog feedback controllers. In Japan, research on automated highway systems was started in the early 1960s in the Mechanical Engineering Laboratory (MEL) and the National Institute of Advanced Industrial Science and Technology (AIST). The automated driving system in 1960s employed a combination of an inductive cable

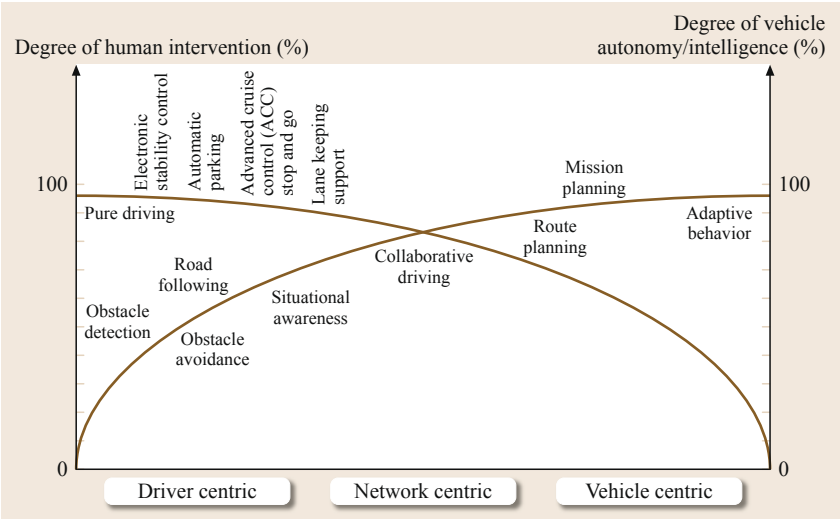

Fig. 62.1 Architectures for autonomous vehicles (after [62.1])

embedded under a roadway surface and a pair of pickup coils at the front bumper of a vehicle for lateral control, and it was a cooperative system between vehicle and infrastructure. In addition to the free agent, a rear-end collision avoidance system between two automated vehicles based on roadway vehicle sensors was developed. The automated vehicle drove up to 100 km/h on a test track in 1967 [62.3].

The history of intelligent vehicles developed further over the ensuing decades. Although the first ideas were born in the 1960s, the level of maturity of the technology at that time did not allow pursuit of the original goal of implementing fully autonomous all-terrain, all-weather vehicles. The first documented prototypes of such vehicles were fielded by a few groups in the military arena in the mid 1980s [62.4–6]. The initial stimulus that triggered these innovative ideas was provided by the military sector, which was eager to provide complete automation to its fleet of ground vehicles.

Testing of autonomous vehicles on real roads in a real environment was one of the most important milestones in the history of intelligent vehicles. In Germany, in the beginning of the 1980s *Dickmanns* and his team equipped a Mercedes-Benz van with cameras and other sensors. For safety reasons, initial experiments in Bavaria took place on streets without traffic. Since 1986 the robot car *VaMoRs* from the same group manages to drive all by itself, since 1987 at speeds up to 96 km/h. A number of these capabilities were also highlighted in the European PROMETHEUS Project. (for example, [62.7])

This happened in the mid to late 1990s. Figure 62.2 shows the first motor vehicles that pioneered the development of intelligent vehicles. In the summer of 1995, the Carnegie Mellon Navlab group ran their *No Hands Across America* experiment [62.8]. They demonstrated automated steering, based solely on computer vision,

over 98% of the time on a 2800 mile trip across the United States. At the same period the EU funded the first large and ambitious project for autonomous car navigation (the EUREKA Project *Prometheus*) involving the major European car constructors and research institutes. In the scope of this project, UBM (Bundeswehr Universität Munich) fielded a vehicle that was demonstrated on a 1758 km-trip from Munich to Copenhagen and back. The vehicle was able to drive autonomously for 95% of the trip. The car suggested and executed manoeuvres to pass other cars. Unlike later robot cars, this car located itself on the current road and followed it until instructed otherwise. It did not localize itself in global coordinates and could drive without a global positioning system (GPS) and road maps as found in a modern automotive navigation systems. The vehicle used dedicated purpose-built computers and hardware.

A different approach was followed by VisLab at the University of Parma within the Argo project. The passenger car that was designed and developed was based on a low-cost approach. An off-the-shelf Pentium 200 MHz personal computer (PC) was used to process stereo images obtained from low-cost cameras installed in the driving cabin. The vehicle was able to follow the lane, locate obstacles, and – when instructed – change lane and overtake slower vehicles. The main milestone of this project was the successful test of the Argo vehicle on a tour of Italy of more than 2000 km called *Millemiglia in Automatico*, in which the vehicle drove itself for 94% of the total distance. Another low-cost approach was developed at INRIA in 1995 for its *dual mode* system, in which a small dedicated electric vehicle was able to park itself autonomously using only ultrasonic sensors and a linear camera.

Through the years, many demonstrations have been held showing the public the capabilities of autonomous vehicles, and by extension, underlining the sensor capabilities at the autonomous driving demonstrations. One of the most comprehensive highway-based demonstrations was held in 1997 on I-15 in San Diego, USA, and showed the capabilities of cars, buses, and trucks in various automated highway scenarios. The demonstration (called Demo'97) was organized by the National Highway Systems Consortium. The key technologies were lane-following using roadway imbedded magnets, roadway laid radar-reflective stripes or using lane markers with vehicle mounted cameras; car following using laser or radar, with or without help of inter-vehicle communication. Scenario maintenance was accomplished by either total preplanning and timing, or by GPS and map-based triggering, or by situation-based triggering [62.9, 10].

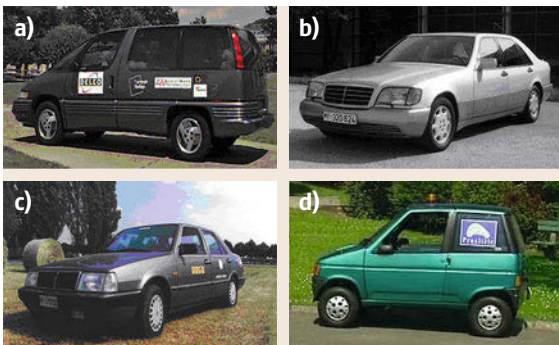

Fig. 62.2a–d Pictures of pioneering autonomous vehicles (a) NAVLAB, (b) UBM, (c) Argo, and (d) Ligier-INRIA electric vehicles

The Demo'97 was followed by a number of demonstrations around the world, notably in Japan, Holland, France, and the US. In each case, not only were state-of-the-art technologies demonstrated, but the public was informed about what to expect in future cars.

In November 2000, the demonstration *Demo 2000 Cooperative Driving* was organized by the National Institute of Advanced Industrial Science and Technology in Tsukuba, Japan. Several platooning scenarios were accomplished by five automated vehicles in the enclosed test field. This platoon of five automated vehicles performed stop-and-go operations, platooning, splitting into two platoons demonstrating an exit ramp, merging into one platoon from two platoons imitating highway traffic at a ramp, and passing by the last vehicles. Furthermore, obstacle detection, platoon leaving, and joining tasks were accomplished. Autonomy was guaranteed by inter-vehicle communication. In addition, vehicles were equipped by differential global positioning system (DGPS) to assure localization by the laser radar to detect obstacles and to measure the relative position between the vehicles. Vehicles of Demo 2000 did not communicate with the infrastructure i. e., road-to-vehicle communication except DGPS. These automated vehicles were autonomously driven by exchanging information through inter-vehicle communication [62.11].

Current research initiatives are oriented towards the development of intelligent vehicles in realistic scenarios. However, until recently, primarily due to legal issues, full autonomy had not yet been set as the ultimate goal. The automotive industry had set as its primary goal the need to equip vehicles with supervised systems and – more generally – advanced driving assistance systems (ADAS) instead of automatic pilots. In other words, the driver was still in charge of running the vehicle, but the driver and vehicle were monitored by an electronic system that detects possibly dangerous situations and reacts by either warning the driver in due time, or taking control of the vehicle in order to mitigate the consequences of the driver's inattention. In spite of the aforementioned legal issues, the ultimate goal has now shifted towards developing self-driving systems and a number of automotive manufacturers have announced such cars in the market by model year 2020. Concurrently, departments of transportation worldwide which have been primarily interested in social, economic, or environmental objectives aimed at enhancing fuel efficiency, road network usage, and improving quality of life in terms of mobility have now shifted their attention to the possibility of mixed traffic on the road, consisting of regular vehicles driven by people and autonomous vehicles [62.12].

Different approaches and research goals have evolved internationally. The USA has pushed for fully autonomous vehicles which could be commercialized, Europe has focused on ADAS systems and public transportation applications, clean vehicles, and free-service autonomous vehicles (Sect. 62.7). This contrast is illustrated by the differences in scope and objectives between US funding schemes and competitions (e.g., DARPA challenges, Google cars) and European projects (e.g., Prometheus, Carsense, Prevent, Inter-safe).

The good results obtained by ADAS in the automotive arena in recent years has induced the military sector to give a new vigorous push to the original ideas of automating its fleet of ground vehicles. The Defense Advanced Research Projects Agency (DARPA) launched the Grand Challenge in 2003, a race for autonomous vehicles that had to travel for more than 200 km in unstructured environments. This unprecedented challenge attracted a large number of top-level research institutes and helped the scientific community take a considerable step forward.

In 2005 the DARPA Grand Challenge required autonomous driving in a rough terrain desert scenario with no traffic, obstacle types known in advance, and few if any road markers on a course predefined by 2935 GPS points [62.13]. Five cars (maximum speed 40 km/h) completed the 211 km desert course, with Stanford's Stanley winning the challenge in 6 h 54 min. Figure 62.3a–b shows photographs of the top two finishing vehicles. The reader is referred to [62.14] for the technical details of the DARPA Grand Challenge.

Following the Grand Challenges, the 2007 DARPA Urban Challenge was performed in *emulated* city traffic and saw the return to urban vehicles [62.15]. Autonomous ground vehicles competed to win the Urban Challenge 2007 prize by accomplishing an approximately 60 mile urban course area in less than 6 h with moving traffic. The autonomous vehicle had to be built upon a full-size chassis compared to production type vehicles and must have a documented safety report. The autonomy capability demonstrated in forms of a complex set of behaviors by obeying all traffic regulations while negotiating with other traffic and obstacles and merging into traffic. The urban driving environment challenged autonomous driving with some physical limits such as narrow lanes, sharp turns, and also by the daily difficulties in a daily urban driving such as congested intersections, obstacles, blocked streets, parked vehicles, pedestrians, and moving vehicles. The winner of the Urban Challenge was Tartan Racing, a collaborative effort by Carnegie Mellon University and the General Motors Corporation, with their vehicle *Boss*, a heavily modified Chevrolet Tahoe. The

second place finisher was the Stanford Racing Team with their entry *Junior*, a 2006 Volkswagen Passat. Figure 62.3c–d shows photographs of the top two finishing vehicles. In May 2011, The Netherlands Organization for Applied Scientific Research TNO, together with the Dutch High Tech Automotive Systems innovation program (HTAS), organized the Grand Cooperative Driving Challenge (GCDC) in The Netherlands. The 2011 GCDC focused on cooperative adaptive cruise control (CACC). Nine international teams participated in the challenge [62.16].

In 2010, the University of Parma's VisLab Intercontinental Autonomous Challenge [62.17–19] further pushed the boundaries by having four driverless vehicles (Fig. 62.3e) drive autonomously 15 000 km from Parma, Italy to Shanghai, China. A more recent example is the Google driverless car (Fig. 62.3f): a fleet of autonomous vehicles which by 2012 had driven more than 480 000 km autonomously. Google has demonstrated fully autonomous driving in dense urban California traffic, utilizing vision-based systems and Google Street View. This activity, repeated in a number of cities generated extensive public interest and led to the belief that autonomous vehicles will be available for public use in the near future. This has been a major factor leading three US states (California, Nevada, and Florida) to approve laws permitting driverless cars. A number of car manufacturers have announced models to come to market by 2020.

62.1.2 Benefits of Intelligent Vehicles

Having intelligent vehicles running on our road networks would bring a number of social, environmental, and economical benefits. An intelligent vehicle able to assess the driving scenario and react in case of danger would allow up to 90% of traffic accidents that are caused by human errors to be eliminated, thus saving human lives. According to the World Health Organization an estimated 1.2 million people worldwide are killed each year, and about 40 times this number injured, due to traffic accidents.

At the same time, vehicles able to drive at high speeds and very close to each other would decrease fuel consumption and polluting emissions; furthermore they would also increase road network capacity. Vehicles communicating with a ground station could share their routes and be instructed to reroute in order to maintain a smooth traffic flow. Vehicles that can sense and obey speed limits or traffic rules would reduce the possibility of misinterpretation and antisocial driving behavior.

Fully automatic vehicles would also offer a higher degree and quality of mobility to a larger population, including young, old, or infirm individuals, reducing the need even for a driving licence. Finally, the availability of vehicles that could drive themselves would increase the quality of mobility for everyone, turning personal vehicles into taxis able to pick up people and take them to their final destination in total safety and comfort, enabling people to dedicate their driving time to their preferred activities.

However, this full application of intelligent vehicles is far from being complete, since unmanned vehicle technology is still under development for many other applications. The automation of road vehicles is, perhaps, the most common everyday task that attracts the greatest interest from the industry. However, other domains such as agricultural, mining, construction, search and rescue, and other dangerous applications in general, are looking to autonomous vehicles as a possible solution to the issue of the ever-increasing cost of personnel. If a vehicle could move autonomously on a field to seed, or enter a mined field, or even perform dangerous missions, the number of individuals put at risk would drastically decrease and at the same time the efficiency of the vehicle itself would be increased due to a 24/7 operational schedule. The key challenge for intelligent vehicles is safety; accidents must not occur due to automation errors and there is zero tolerance to human injury and death.

This chapter focuses on road and traffic applications of intelligent vehicles, which are catalyzing the interest of the automotive industry, car makers, and providers of automotive technologies.

62.2 Enabling Technologies

The basic sensing and actuation technologies for intelligent vehicles are readily available on the market. The key challenge to integrating new technologies is heavily dependent on the control strategies associated with the sensor data processing and reasoning. Automated systems must consider all subsystems in a vehicle, including the interaction of the technology with the driver. Key drivers for the new technologies in an intelligent vehicle are the desired applications. Solutions are developed on the premise that the system must satisfy the requirements of the application with the minimum level of technology.

Intelligent vehicle applications require the following:

- The position, and kinematic and dynamic state of the vehicle
- The state of the environment surrounding the vehicle
- Access to digital maps and satellite data
- The state of the driver and occupants
- Communication with roadside infrastructure or other vehicles.

62.2.1 Vehicle State

Position localization is a key technology for intelligent vehicles. The position of the vehicle must be known if the vehicle is to be controlled along a particular trajectory. To control an intelligent vehicle to perform applications such as collision avoidance or automatic lane changing requires knowledge of the kinematic and dynamic states of the vehicle. Standard robotics techniques for position, kinematics, and dynamics are used in intelligent vehicle applications (Chap. 34). Encoders are mounted on the steering column and the tail shaft. Vehicle heading, speed, and acceleration can be computed from the encoders using standard techniques (Chap. 24).

To execute the trajectories in an intelligent vehicle a number of techniques are used. In many current applications of fully automated vehicles, the trajectories are fixed with limited choices at intersections. To execute the trajectories, the vehicles simply follow markers such as an antenna (a wire carrying an alternating current), magnets, or passive transponders such as radio frequency identification (RFID) tags that are imbedded in the road or simple painted lines. In more advanced navigation systems, the vehicle generates trajectories in a map stored in its memory and localizes itself with respect to this map in order to execute them. This localization can be done using absolute positioning through

a combination of global navigation satellite systems (GLS), vehicular kinematic states, and inertial navigation. Alternatively, position localization can be done by relative localization using local markers such as visual landmarks. (For specific reference to earlier mobile robot landmark navigation see Chap. 46.)

In order for the vehicle to execute trajectories, it needs to control the speed and the steering of the vehicle (Fig. 62.4). Modern vehicles now incorporate electronic control units to control the acceleration (motor torque and possibly gearbox and clutch), the braking (electric or electrohydraulic brake control), and the steering angle (electric power assistance), and it is, therefore, quite easy to implement trajectory control of the vehicles [62.20]. The safety of these critical functions remains a challenge, and is usually solved through redundancies in the sensors, actuators, and control units.

62.2.2 Environment State

Sensing the state of the environment surrounding the vehicle is a critical aspect of intelligent vehicle applications. The most difficult function for intelligent vehicles is road scene understanding. This includes locating key landmarks: the road, other vehicles, pedestrians, traffic signals, road signs, and other unstructured obstacles. A more difficult challenge is speed control following the detection of an event in the road scene. Com-

Fig. 62.4 Ackerman steering model

Fig. 62.5 Environment state sensing

mon sensors are infrared [62.21], ultrasound [62.22], radar [62.23], laser range finders [62.24], and computer vision, which continually scan the environment, as shown in Fig. 62.5. Radar is generally used for obstacle detection at a distance, while infrared and ultrasound are used for close proximity obstacle detection. Laser ranging and image processing are used to more robustly recognize the road scene under various weather conditions. Certain road scene conditions such as road signs and traffic lights can only be understood using vision sensing. Sensor fusion is commonly used in intelligent vehicle applications, due to the complementarity of heterogeneous sensor modalities; this can greatly improve perception, for instance, between monocular vision and radar/laser sensors. Sensor fusion (Fig. 62.5) is critical technology for intelligent vehicles and constitutes a wide and active research field for both research teams and automakers (Chap. 35) (Fig. 62.6).

Using such sensors it is possible to map the environment surrounding the vehicle and then, using techniques such as simultaneous localization and mapping (SLAM) (Chap. 46), generate the complex maneuvers needed for parking or for obstacle avoidance.

62.2.3 Digital Maps and Satellite Data

Other additional sensing is generally delivered by global positioning technologies (for example, GPS) to map the vehicle position and refer it to a description of the world known a-priori. This mapping procedure may also be very precise in some areas (like cross coun-

try roads) and may be particularly noisy in others (like downtown areas). To fix issues related to multi-path measurements and to fill gaps when the GPS signal is missing, inertial measurements units (IMU) are generally used together with GPS.

Combining GPS with stored digital maps creates a wide variety of intelligent vehicle applications [62.27]. Map data can greatly assist in the problem of road scene interpretation, map data can improve lane detection quality, help deal with the problems when sensors such as cameras do not work, e.g., in sunlight, at dusk, or dawn. Digital maps are widely

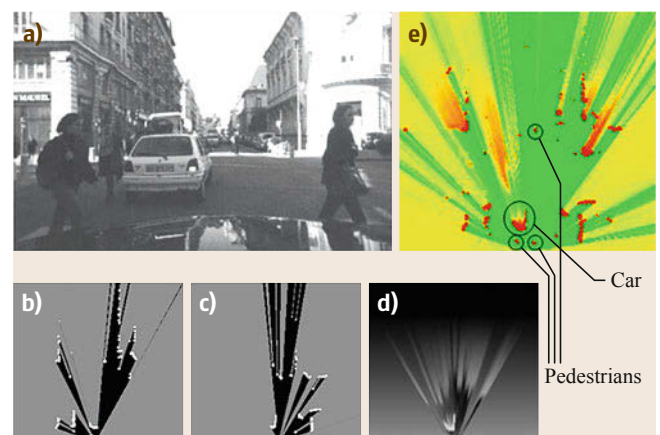

Fig. 62.6a–e Multi-sensor fusion on a Toyota/INRIA experimental vehicle (after [62.25, 26]). (a) Urban scene as seen from a car, (c) occupancy grids, (d) lidar, (e) occupancy grid from a stereo camera, (b) fused data and detected objects

used in commercial navigation systems for route guidance [62.28] and are updated frequently. Such systems will be improved when real-time updating of the map will occur due to the availability of traffic information [62.29]. Additional functionalities to be added include curve approach warnings [62.30], curve speed control [62.31], traffic sign information, and speed limit information [62.32], as well as predetermining an appropriate heading of the headlights in curved and hilly roads.

62.2.4 Driver State

Additionally an intelligent vehicle needs to understand the driver state, if it is to give appropriate warnings or take action. Vision sensors [62.33] can monitor a driver's attentiveness and fatigue by observing the direction of the driver's gaze and eyelid behavior. In an emergency, knowledge of the position of the driver's head as well as all other occupants' position and posture can assist in the safe deployment of airbags. Also, after an accident, observing the state of the driver and other occupants could be useful for the dispatch of emergency services to the accident scene.

62.2.5 Communication

Communication technologies enable interesting applications of intelligent vehicles. Allowing vehicles to communicate with each other and with the highway offers the prospect of vast improvements in the safety and efficiency of the road system. Applications include intersection collision avoidance, emergency braking, and sharing of road and traffic condition information.

The basic communication modes are distinguished as:

- Vehicle to/from roadside infrastructure
- Vehicle to vehicle.

Dedicated short-range communications (**DSRC**) have been set up to from the vehicle to infrastructure communications to support traveler information, commercial applications (toll/parking fee collection, in-vehicle advertising), and safety applications (intersection collision avoidance, approaching emergency vehicle warning, and rollover warning) [62.34].

DSRC is a wireless protocol specifically designed for intelligent transportation systems. It is a subset of **RFID** technology, working in the 5.9 GHz band (US) or 5.8 GHz band (Japan and Europe). It is generally implemented with a dedicated protocol, uses short messages, and works in direct line of sight over short ranges (10–1000 m).

Specific applications are being developed to test a broad variety of potential safety and mobility uses of the systems including:

- Warning drivers of unsafe conditions or imminent collisions.
- Warning drivers if they are about to run off the road or speed around a curve too fast.
- Informing system operators of real-time congestion, weather conditions, and incidents.
- Providing operators with information on road capacity for real-time management, planning, and provision of road advisories to drivers.

For intelligent vehicles safety-related applications using **DSRC** include:

- Stopped vehicle or obstacle avoidance of obstacles on highways.
- Merging assistance from a slow incoming lane into a crowded road.
- Intersection safety and collision warning systems (with or without traffic lights).
- Establishing and maintaining convoys/platoons.

In a vehicle-based intersection collision warning system, each vehicle approaching the intersection generates a message. The message includes the vehicle's location, direction of travel, and the intersection location. This information is based on the **GPS** position and available map data base. Various strategies to predict driver intention are also being studied, and if available this information is also broadcast. Any other vehicle approaching the intersection can calculate the possibility of a collision and will generate an appropriate warning for its driver.

There numerous other possible applications. These include:

- Notification of the presence or approach of an emergency vehicle
- Notification of construction activity
- Local multi-vehicle sensor fusion to provide better global maps and situation awareness
- Energy saving applications (platooning, energy management for HEVs in stop and go traffic).

The USA, since 1999, and the EU, since 2008, have located spectrum in the 5.9 GHz band for wireless **DSRC** systems for vehicular safety and intelligent transportation system applications. The standards for **DSRC** in the US are IEEE 802.11p, finalized in 2010, and wireless access in vehicular environments (**WAVE**) (IEEE 1609), still in draft status as of July 2010. The 802.11p standard is derived from the 802.11A wireless LAN standard and thus provides a fairly easy and inexpensive route to produce communication electronics

and hardware. These standards provide network and application support, as well as sufficient range and data rates, for both V2V and V2I communication applications.

In addition to wireless communication standards, the development of standardized message sets and data definitions in the US has occurred in the SAE J2735 standards process.

The **WAVE** standard supports two types of devices, the roadside unit (**RSU**), and the on-board unit (**OBU**). The **RSU** would typically be a service provider deployed on the roadside that would provide map data like the geometric intersection data (**GID**) message. If it is connected to a traffic light it could also provide signal phase and timing (**SPaT**) messages. Both message types are defined in SAE Standard J2735 [62.35]. The **OBU** is responsible for receiving data from **RSUs** and generating and receiving safety messages that relay information about the vehicle's current state. Many investigations of the utility and capabilities of these

standards exist [62.36] and large-scale testing is underway in the US within the *Connected Vehicle* program.

For vehicle-to-infrastructure communications [62.37], a communication protocol architecture is currently being specified by the ISO-SAE Technical Committee 204 Working Group 16 [62.38]. This protocol architecture is known as communication access for land mobiles (**CALM**) [62.39] and is being implemented in Europe under the cooperative vehicle infrastructure systems (**CVIS**) integrated project [62.40]. **CALM** is based on IPv6 protocols developed by the Internet Engineering Task Force (**IETF**) [62.41], particularly the network mobility (**NEMO**) protocol, which allows sessions to be maintained between an in-vehicle internet protocol (**IP**) network and the Internet backbone using any type of available media (3G, general packet radio service (**GPRS**), Wi-Fi, WiMax, M5, **DSRC**, satellite, etc.). For vehicle-to-vehicle applications, systems that support ad-hoc networking are still in early stages.

62.3 Road Scene Understanding

Perception plays a key role in any robotic application. In the case of intelligent vehicles, the perception task is referred to as road scene understanding. It involves using different sensors (described in Sect. 62.2) combined with automatic reasoning, in order to create a synthetic representation of the environment around the vehicle. The knowledge base accumulated by this task is then used either to issue warnings to the driver in the case of advanced driving assistance systems (**ADAS**) or to control vehicle actuators in the case of complete autonomous driving. A complete and precise description of the state of the surrounding environment is the key factor that allows the reduction of the number of false and missed alarms and provides the basis for smooth automatic driving. Needless to say, the perception of an outdoor environment – even if partially structured – is a challenging problem not only due to the intrinsic complexity of the driving environment itself, but also due to the impossibility of controlling many environmental parameters. Figure 62.7 shows examples of day/night, sun/streetlight illumination, temperature, poor visibility, rain/snow, and different meteorological conditions, which in general are impossible to control and have to be faced by sensing devices.

The research community is addressing the issue of providing vehicles with robust and precise perception of the state of the environment from two different perspectives. One approach is to provide vehicles with ever-increasing sensing capabilities and processing power aimed at the provision of powerful onboard intelligent

systems; [62.42]. An alternative approach is to use road infrastructure as an active component capable of communicating with all vehicles and sharing information on road conditions in real time [62.43]. Indeed, these

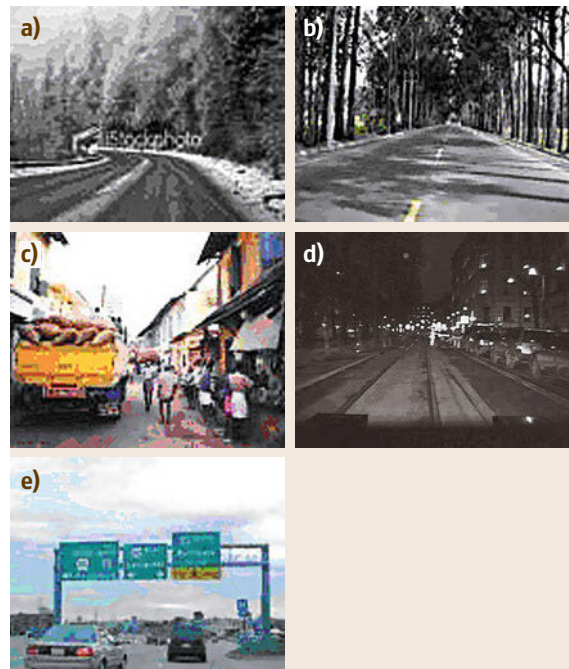

Fig. 62.7 Typical range of road scenes that intelligent vehicles must handle

two perspectives can also be merged to provide a mixed solution to safely control a vehicle and in dynamic environments [62.43].

The task of road scene understanding may be addressed differently, depending on the availability of an intelligent infrastructure and on other players exhibiting cooperative behavior. The task of understanding the state of the environment can be simplified through the availability of information coming from other sources, thereby limiting the need to perform a robust and complete sensing onboard each vehicle. Helpful information could come from the infrastructure itself (for example, road conditions and geometry, number of lanes, visibility, road signs, or even real-time information such as traffic-light status or traffic conditions) or other players (such as the presence of the vehicle with precise position, speed, and direction). The players may also carry real-time information gathered by and shared with other players.

Although research is currently focused on both intelligent vehicles and intelligent infrastructures, the first generation of production intelligent vehicles will have to rely primarily on their own sensing capabilities, since the availability of information coming from other sources such as the infrastructure and other vehicles will take a while to be deployed in real-world situations. In fact, in order to be of practical use, intelligent roads must cover a large proportion of a country, and simultaneously cooperative intelligent vehicles must also be sufficiently widespread. It is important to note that the investment in intelligent infrastructures and intelligent vehicles comes from different sources: mainly from governmental institutions for the former, and vehicle owners for the latter.

The information that is owned by the infrastructure itself and that could be made available to the vehicles includes:

- Precise geometry of the lane/road
- Road signs
- Status of traffic lights.

On the other hand, the infrastructure can also assess and deliver real-time data such as:

- Road conditions
- Visibility
- Traffic conditions.

Another important piece of information that needs to be gathered by intelligent vehicles is the presence of other road players, such as:

- Vehicles
- Vulnerable road users (pedestrians, motorcycles, bicycles).

Although it could be assumed that sometime in the future all vehicles will be equipped with active systems that allow them to be safely avoided by other vehicles, it is quite improbable that pedestrians and bicycles will have similar equipment; their presence will need to be detected using onboard sensors only. The same consideration also applies to obstacles that may unexpectedly be found on the road, or to temporary situations such as roadwork; if a vehicle needs to cope with the unexpected, then it needs to have the capability to assess the situation in real time with its own sensors.

This is why onboard sensing is of paramount importance for future transportation systems; vehicle-to-vehicle and vehicle-to-infrastructure communications may help and improve the sensing, but a complete sensor suite must also be installed on our future vehicles. The main challenges in road environment sensing are examined below.

62.3.1 Road/Lane Tracking

Many vehicle prototypes have been equipped with lane detection and tracking systems, starting from the very first implementations in the early 1980s [62.4–6]. Indeed, in this case computer vision plays a basic role; although generally the road can also be detected with laser scanners [62.24], the only generic technology able to detect lane geometry and lane markings with high precision is computer vision. Most lane tracking approaches have focused on detecting lane markings and exploiting structure in the environment, such as the parallelism of the left and right lane markings, the invariance of road width, or the widely used flat-road assumption. These assumptions were mainly used to overcome the problem of having a single camera (a choice driven by cost). Some systems use stereo vision to detect lane markings and are able to work without such constraints. The problem of lane tracking in highway situations is basically a solved problem – with commercial systems being deployed in passenger and

Fig. 62.8 Lane detection

commercial vehicles. A survey and evaluation of the deployed lane tracking technologies is available [62.44]. An example of the typical output of a commercial lane tracker is shown in Fig. 62.8.

However, such systems cannot guarantee that lane detection systems will work with 100% reliability; these systems typically work with 95–99% reliability. Therefore, lane tracking systems are only being used in lane departure warning systems, since no failures can be tolerated for autonomous driving. Efforts are underway to develop algorithms that will tolerate a variety of driving conditions, and push the 100% reliability boundary [62.44, 45],  VIDEO 836.

Vision-based lane tracking systems depend on lane markings, which are not always present. In these cases it is often not enough to track the lane or road's limits. Instead it is necessary to build a local representation of the road's shape and traversability. This local map can be built using SLAM-like techniques (Chap. 46), and can classify parts of the map as either static or dynamic [62.46]. Alternative approaches aim to classify 3-D points obtained from laser scanners or stereo cameras as belonging to the road or not [62.47]. The output of the road detection function is a continuously updated representation of the *navigable space* in front of the vehicle (Fig. 62.9).

62.3.2 Road Sign Detection

Another fairly straightforward use of computer vision is road sign detection and understanding. Road signage is deliberately structured to aid human drivers. Road signs use a set of well-defined shapes, colors, and patterns. The signs are placed at consistent heights and positions in relation to the road. Therefore, reading road signs is an achievable task for computer vision. Detection is done using a collection of shape and/or color detection schemes [62.48, 49]. After the detection and localization phase, recognition takes place. Normally this task is performed by pattern-matching techniques such as image cross-correlation, neural networks, or

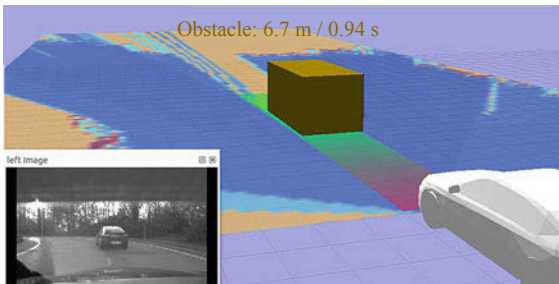

Fig. 62.9 Instantaneous representation of the navigable space in front of the vehicle (after [62.25])

support vector machines, since the possible set of road signs is limited and well defined. Figure 62.10 illustrates the concept of a speeding warning system based on speed sign detection. The challenge for research work in this area lies in the robustness of detection and the reliability of classification of signs. Most automotive companies have systems under development, e.g., Siemens [62.50]. See video on speed sign detection  VIDEO 838.

62.3.3 Traffic-Light Detection

Color and pattern matching are also the key techniques used for the detection of traffic lights [62.51]. Although the detection of traffic lights is not overly complex, this application hides one further aspect that makes vehicular applications difficult: besides the correct localization and recognition of a signal, special care has to be taken in checking the signal position and orientation on the road/lane since that signal may not be addressed to the current vehicle. This is particularly true in downtown intersections at which many traffic lights are visible at the same time; in this case the vehicle must have the capability to select the correct traffic signal that must be obeyed. Some experiments have been undertaken with active traffic signals, able to emit the status of the traffic light using radio frequencies [62.52]. This involves additional infrastructure; at this stage vision seems to be the only simple viable solution.

62.3.4 Visibility Assessment

One of the key challenges is the detection of fog. The meteorological visibility distance is defined by the International Commission on Illumination (CIE) as the distance beyond which a black object of an appropri-

Fig. 62.10 Road sign detection for speed warning application

ate size is perceived with a contrast of less than 5%. Different techniques for measuring this parameter – and thus detect foggy conditions – have been implemented [62.53]. Although many of the methods use vision, there are also efficient alternatives – generally used in fixed locations such as airports and traffic-monitoring stations – based on the use of multiple scattering lidar. The main challenge of using vision to estimate visibility is that a moving vehicle generally cannot rely on a specific reference point/object/signal at a specific distance.

62.3.5 Vehicle Detection

The detection of vehicles has been addressed using a large variety of sensor technologies, ranging from vision to lidar, from radar to sonar.

Despite being different in shape and color, vehicles share the same characteristics and feature a large size and reflective material. The position of vehicles is predictable once a rough indication of the road/lane position is available. Vehicles, in fact, can be suc-

cessfully detected by many different sensors independently [62.55–57]. Figure 62.11 shows a vision-based vehicle detection system.

Nevertheless, although the solution to this problem seems straightforward, each sensor has its own domain of application and its own challenges. Vision is generally powerful, but may fail in low visibility and bad-illumination scenarios (night or tunnels) or in heavy traffic conditions when vehicles may occlude each other. Vision in the infrared domain (thermal imaging) is able to detect vehicles with a high confidence since vehicle tires and mufflers generally exhibit high temperatures and are, therefore, easily detected in the image. However, parked vehicles, trailers, and even vehicles which have just started to move are colder than running vehicles and, therefore, less visible. Lidar is generally robust, but has decreased sensitivity in adverse weather conditions. Radars, while cheap, can suffer from bias in lateral measurements due to the presence of other nearby reflecting objects. Finally, sonars are applicable only for very short distances. The research challenge is to implement multisensor fusion robustly. A common approach is to fuse vision with radar [62.58].

Vehicle detection is often performed by grouping together data that are believed to belong to a same object, this often implies using some kind of similarity metric based in distance and other relevant features such as color, and texture, etc. An alternate approach is taken by *model based* techniques, which scan scene data trying to match models from a pre-existing catalog – e.g., geometric descriptions, part collections. Finally, *grid-based* approaches do not directly model objects themselves, but the evolution of the properties in a regular decomposition of the space (Fig. 62.12) [62.54].

Fig. 62.11 Vehicle detection – lane and range position

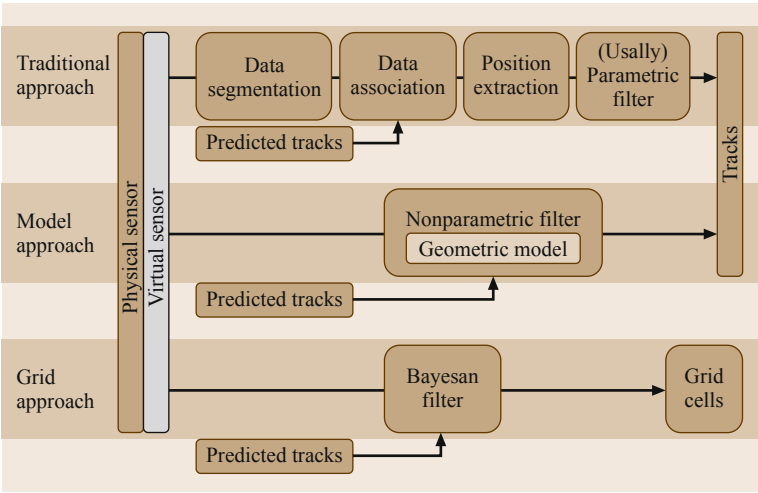

Fig. 62.12 Three alternative approaches to vehicle detection and tracking (after [62.54])

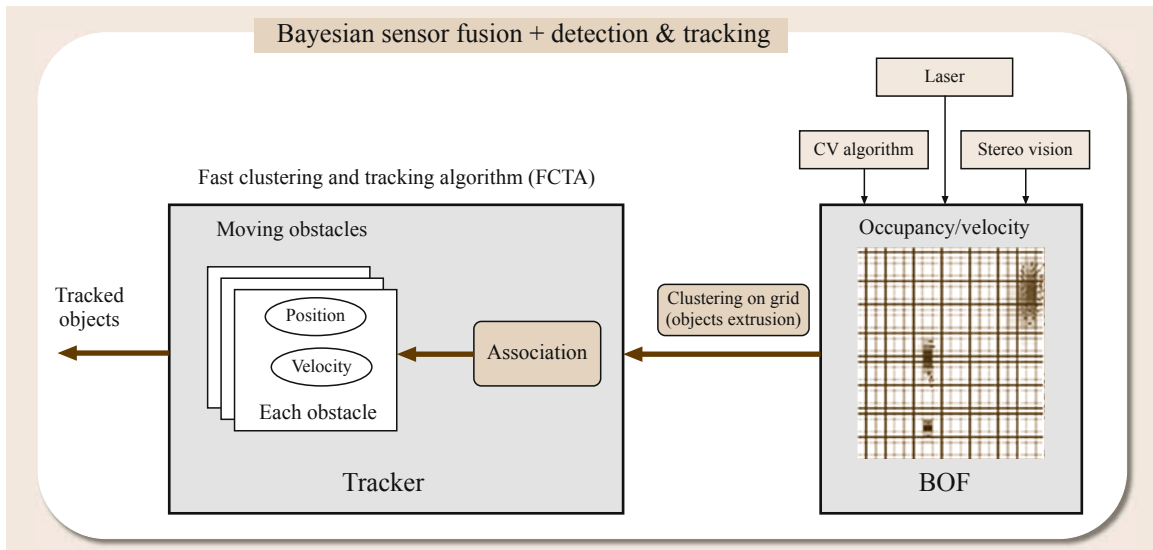

Fig. 62.13 Grid-based detection and tracking (after [62.59])

One of the main problems in tracking is *data association*: finding the correspondence between sensor readings and tracked objects. Tracking approaches differ in the way they solve this problem from the *nearest neighbor*, which just assigns the observation to the closest object to multi-hypothesis tracking (MHT), which maintains a representation of the different association hypothesis for several time steps – pruning is necessary for tractability. An increasingly popular alternative is the use of grid-based approaches, which do not attempt to explicitly represent objects during the iterative grid updates while taking into account all the possible associations with cells in a given neighborhood. This approach leads to postponing as long as possible the object detection and data association steps [62.54]. Refer to Fig. 62.13 for an example of grid-based tracking. [VIDEO 420](#) shows the predictive capabilities of the Bayesian occupancy approach [62.59].

62.3.6 Pedestrian Detection

The detection of vulnerable road users (pedestrians and bicycles) is one of the most difficult tasks for intelligent vehicles. The appearance of a pedestrian is challenging: a pedestrian shape can change greatly within a few

tens of milliseconds; there are no clear invariants in color, texture, or size, and no assumptions can be made about posture, speed, or the visibility of parts of the human body such as the head. Machine learning methods have been successfully applied to this problem [62.24, 42, 48, 60]. The focus is on achieving greater reliability and reduction in false alarms through improved vision algorithms [62.61]. However, the detection of vulnerable road users is one of the most relevant research topics worldwide since a great number of benefits – including insurance reductions – may be achieved once a fully functional pedestrian detector is available on cars. Countermeasures may be activated to reduce the consequences of vehicle–pedestrian accidents, such as the firing of external airbags or the opening of the hood to lessen the impact of a head-on collision. Currently, with all possible technologies under evaluation, no solution seems to offer reliable detection in every scenario: radars are not able to detect pedestrians reliably in crowded scenarios, while vision has the many drawbacks listed above. Even thermal imaging, which – although still very expensive – is generally believed to be one of the most promising technologies, fails in some situations, such as hot summer days and, in general, in high-temperature environments. See video for vision based stereo vision detection [VIDEO 839](#).

62.4 Advanced Driver Assistance

Given the legal liabilities and technical challenges of achieving 100% reliability for autonomous intelligent vehicles, it appears likely that motor vehicles will have

pieces of autonomous functionality added progressively and that cars will eventually evolve into autonomous robots. The perception techniques described earlier can

be used in a variety of ways to make driving safer, more efficient, and less demanding. Individual perception techniques, or combinations of sensing modes, are being used to provide warnings to drivers of dangerous situations. These warnings are being used to prevent collisions in a variety of situations, such as when backing up, when leaving a roadway, into rear ends, on lane changing/merging, with pedestrians, and at intersections.

Developing a collision warning system requires many steps beyond building the perception system. For a typical example, roadway departure warning, the steps followed in a program initiated by the US National Highway Traffic Safety Administration include:

1. Statistical studies. In the United States, crashes involving a single vehicle leaving the roadway are relatively rare, but disproportionately dangerous; approximately 40% of the 40 000 fatal crashes per year in the US are single-vehicle crashes where the vehicle leaves the roadway. The first part of the study looked at the prevalence of those crashes, and determined that this would be a good type of crash to prevent.
2. Causal factors. The second step was to determine the causes of those crashes. Most run-off-road crashes are due to driver factors, such as excessive speed, inattention, or loss of control. This is an important observation, because it means that alerting the driver, or warning of difficult situations, could prevent those incidents. For the fraction of crashes caused by mechanical failure a warning system would not be useful; in this type of crash, mechanical failure is involved in less than 5% of the crashes.
3. Opportunities for intervention. This part of the study set out to determine whether a warning system could be effective, and, if so, how far in advance the warning would have to be given. Given typical road departure trajectories, typical widths of roads and shoulders, and the range of potential steering responses, this task generated requirements for how accurately the system would have to track vehicle trajectory in order to predict a roadway departure.
4. Human factors. Since the system being designed is a warning system, rather than an active control, it is crucial to understand what kinds of warning a driver (who may be distracted or sleepy) would respond to, and how quickly and accurately the response will be. Reaction times vary widely across individuals: using 1 s for reaction time is a fairly standard estimate.
5. Simulator studies. A driving simulator is like an aircraft flight simulator for cars or trucks, with a va-

riety of simulated roads and conditions. Simulator studies were used to test driver response to warnings: directional or nondirectional audio warnings, steering wheel shakes, and combinations. A nondirectional audio cue worked best.

6. System specification development. Based on the preceding steps, in order for a system to be useful, it needs to work at day and night, in almost all weather conditions, it needs to measure vehicle speed, lateral position relative to the road, lateral heading, and roadway curvature, and predict future vehicle trajectories long enough in advance to trigger a warning alarm.
7. Perception and system development. Given those specifications, there are several ways that a perception system could be built to sense the road and the vehicle's trajectory relative to the road. For this particular test, a lane keeping system – the Rapidly Adapting Lane Position Handler (RALPH) was developed and tuned [62.62].
8. Limited tests. The entire system – sensors, processing, driver interface – was built and tested with a limited number of volunteers, and the system tuned and validated.
9. Full-scale operational tests. The system was deployed in test fleets, including long-haul trucks and passenger cars.

62.4.1 Collision Avoidance and Mitigation

The complete cycle from the idea of using perception to prevent crashes, to full system development, took over 10 years in this case. The pure *robotics* part of the system is a crucial element, but is only one piece of the development needed to make a useful product. Some active control has already been assumed by today's vehicles. Antilock brakes have been on the market for many years. Traction control systems which control throttle to stop wheel spin are being introduced. Electronic stability control systems take this the next step further, controlling throttle and individual wheel brakes to help in cornering performance. So, gradually, people are willing to cede some control to very reliable automated systems. We can expect this trend to continue.

Each collision warning type has its own list of specific development challenges, as described below.

Backup Collisions

The sensing challenge is to see relatively small objects, such as fence posts or children's toys, while not picking up false alarms from pavement joints or leaves and debris. The sensors used in today's commercial vehicles are piezoelectric ultrasonic sensors, which are inexpensive [62.22]. However, ultrasonic sensors have

well-known limitations. The challenge of developing low-cost, accurate, reliable sensors remains.

Rear-End Collisions

These are among the most difficult collisions to prevent, with the most challenging sensing conditions. Rear-end collisions often happen at high speeds, requiring long-distance sensing of other vehicles (up to 100 m at US highway speeds, much longer at the high speeds found on some European roads or for the longer braking distances needed for heavy trucks). That in itself is not too demanding a challenge: the sensed objects in this case are relatively large and have high metal components, so radar and lidar are both feasible sensing modes. The biggest range-sensing challenge is sorting out true targets (slow or stopped vehicles) from false targets (overhead signs or bridges, and side lobes from strong reflectors on the side of the road). It is also important to determine if the sensed vehicle is in the same lane as the smart car, or a different lane. Sensing lane markings at such a large distance is a very difficult challenge; merging lane sensing (often done by vision) with obstacle sensing (by a different sensor) and registering the two to within the resolution of a lane is a daunting task. This technology remains under development through industry and government programs [62.63].

Lane-Change/Merge Collisions

In the simplest case, the countermeasure to this kind of collision involves short-range sensing to cover the *blind spots* on the rear corners of a vehicle, where it is difficult to see with mirrors. For passenger cars, this area is quite small, and can be covered with a single sonar or radar. Often, the user interface is a warning light placed in the rear-view mirrors [62.64]; this reinforces good driver behavior of checking mirrors before changing lanes. The sensing challenge for heavy trucks or transit buses is the same as for cars, except that the area not visible in planar mirrors can be much larger. Figure 62.14 shows examples of blind-spot detection for cars and heavy vehicles.

The usual solution is a row of sensors along the side of the vehicle, although scanning lidar or panoramic vision have been used in experimental applications [62.65]. The further complication for lane-change warnings is in high-speed driving, where it is important to look not just adjacently to the vehicle but a long way to the rear, to find overtaking vehicles with high relative speeds. The first commercial product was brought to market in 2007 [62.66].

Pedestrian Collisions

Pedestrians are particularly important to detect, because pedestrians are much more vulnerable than people in

Fig. 62.14 Blind-spot detection

vehicles; as discussed earlier they are also, unfortunately, relatively difficult to detect and very hard to predict. Just detecting a pedestrian is not sufficient. In transit operations, for instance, a bus operates close to pedestrians much of the time. To do meaningful collision warning, it is important to detect the pedestrian, detect their current path, look for cues such as crosswalks or curb edges that modify the probability of the pedestrian's trajectory, and match all of these factors with the predicted trajectory of the vehicle. It is crucial to tune the warning system to produce few false alarms while not missing real alarms. A particularly dangerous situation is pedestrians slipping and falling underneath a bus: these are very dangerous situations, but very difficult to detect in time to warn the driver. For these reasons, automotive manufacturers have worked on products such as night vision to enhance driver perception [62.67]. Car manufacturers are bringing to market products that use a data-fusion approach combined with radar-vision for emergency breaking in pedestrian collision situations [62.68].

Other Obstacle Collisions

Vehicles have collisions with many things other than other vehicles and pedestrians, for example, animals (deer, dogs, cats), car parts (tire carcasses, rusted-out exhaust systems), cargo that falls off trucks, construction debris, etc. Warning drivers about these kinds of objects on the roadway is a challenging task. A commercial product for safety systems detects large animals

Fig. 62.15 Animal detection

(Fig. 62.15) using vision and radar sensors [62.69]. A piece of construction timber on the roadway may be large enough to do significant damage to a car, but be small enough to be difficult to see, and be invisible to radar. Some interesting work has been done with high-resolution stereo vision [62.70], with polarimetric radar [62.71], and with high-resolution scanning laser range-finders [62.72]. However, in general, this remains a difficult problem.

Other Actions

Besides warning the driver, there are other actions that an intelligent vehicle can take short of assuming control. If a collision is inevitable, particularly from the side of the vehicle where there is limited crush space, the system can brake and deploy airbags even before physical contact. Of course, such a system would have to be nearly 100% reliable. More simply, if the system senses an imminent front collision, it can preload the power brakes, saving fractions of a second in brake reaction time. The driver must still actuate the brakes, but the onset of hard braking can be much quicker. At 100 km/h, a 0.1 s saving in braking actuation saves approximately 3 m of stopping distance, which can be

the difference between a severe rear-end collision and a much lighter crash. Such systems are being introduced into the high-end market by all the major automotive manufacturers.

Collision Avoidance

The next step beyond emergency braking is an automated system. Such systems have several advantages over a human driver: they have much quicker reaction times, access to sensors such as individual wheel speeds and slips plus external sensors such as radar or lidar, access to individual brake controls and other controls, and so forth. So, if the system had ideal situational awareness, it could, in many cases, do a better job of avoiding a collision than a human could. This is still a very difficult area for implementation, however. First of all, the human has access to higher-level knowledge: the driver may be watching the behaviors of other cars, may make eye contact with pedestrians or drivers, may be watching a policeman directing traffic, etc. So it may be that a maneuver that, to the system, looks like the best way to prevent the collision, is actually the wrong action to take. Secondly, in most countries, as soon as the vehicle takes control there is a shift in the liability for any resulting crash from the driver to the manufacturer. So there is a great reluctance to take active control. An alternative, recently developed approach is to observe the environment state with lidar, and monitor the dynamic vehicle state to determine whether the accident is unavoidable. If the driver can no longer take corrective action, that is, brake or turn away safely, then emergency braking occurs [62.24, 73]. For now, however, active collision avoidance remains a research area, with significant questions of reliability, human factors, and liability.

Traffic Situation Awareness

Traffic situation awareness is a higher level of understanding that is required for decision making in traffic situations. For instance, knowing that a vehi-

Fig. 62.16 A collision warning system for intersection safety implemented on communicating Renault experimental vehicles using the intention/expectation approach (after [62.26])

cle is traveling in the wrong direction along a street is much more informative for estimating the risk of the current situation than knowing its velocity. Thus, traffic situation awareness is emerging as a new area of research effort to understand and reason about the future motion of pedestrians and vehicles. The obtained predictions can then be fed to a motion planning algorithm, which can use this information to minimize collision probabilities [62.74, 75]. Motion models can be used to infer the maneuver intentions of drivers to change lanes [62.76], overtake another vehicle [62.77], make a turn at an intersection [62.78], or comply with the traffic laws at an intersection [62.79]. **VIDEO 566** shows how an embedded Bayesian perception system have been implemented on an experimental vehicle.

Intersection Collisions

Intersection collisions are particularly difficult to prevent because they often involve challenging sensing scenarios. Many of these collisions involve occluded vision, with lines of sight blocked either by large vehicles or by adjacent buildings. They also often involve high closing rates from oblique angles, making it necessary to see a long distance with a very wide field of view. The solution that is usually proposed is to add intelligence to the infrastructure, either in fixed sensing (such as radars looking down each approaching road) or in some kind of radio relay that takes data from approaching smart cars and passes it to other approaching vehicles. All of these solutions are challenging; the large number of intersections makes it difficult to envision any universal solution.

A complementary approach to traffic situation awareness is *risk estimation*, where the objective is to determine how dangerous each potential maneuver is for the vehicle. The classic approach is to use motion models to predict the possible future trajectories for all the dynamic objects in the scene, and then compute the probability of a collision between each possible pair of trajectories for each object. Popular approaches for generating possible future trajectories include rapidly-exploring random trees [62.80], Gaussian processes [62.25, 81], and stochastic reachable states [62.82]. A major limitation of this classic approach to risk estimation is its computational complexity. A recent approach to risk estimation has been proposed, which detects conflicts between the *intentions* of drivers and the *expected* behavior of the vehicle, rather than by detecting collisions between possible future trajectories [62.26, 83] (**VIDEO 822**). More specifically, dangerous situations are identified by comparing *what drivers intend to do* with *what*

drivers are expected to do according to the traffic rules. This formulation of risk reflects the fact that most accidents are caused by driver error [62.84], and matches the intuitive notion that *dangerous* situations are situations where drivers act differently from what is expected of them. This approach can in theory be applied to any traffic situation, but so far has been implemented and tested for scenarios involving cars at road intersections only (Fig. 62.16). Significant research projects are underway in the EU for cooperative vehicle infrastructure projects such as managing intersections [62.85].

Currently, automotive manufacturers are dealing with traffic situation awareness by specifically focusing on discrete driving tasks and typical scenarios. Combining perception with control gives partial automation for specific tasks, such as adaptive cruise control, lane keeping, assisted parking, and slow driving in stop-and-go situations.

62.4.2 Adaptive Cruise Control

Adaptive cruise control (ACC) is the logical extension of standard cruise control to also include keeping a safe distance from the preceding vehicle. If there are no vehicles in front of the smart car, it follows a set speed, as with standard cruise control. If a slower-moving vehicle is in front, an ACC-equipped car will sense the vehicle using radar or lidar, and slow to maintain a safe distance (typically set to a 1.5–2 s following gap). Figure 62.17 shows an illustration of the ACC concept. The sensing challenge for ACC is much easier than the challenge of rear-end collision countermeasures, since ACC systems are only designed to deal with other moving vehicles.

The biggest sensing difficulty for rear-end collision countermeasures is separating stopped vehicles on the road from objects off the road; for ACC this difficulty is bypassed by ignoring all stopped objects. Moving objects are classified as in-lane or out-of-lane based on

Fig. 62.17 Advanced cruise control (ACC)

a number of heuristics. Often, the smart car's own steering radius is used as an estimate of the road curvature ahead, in order to determine whether vehicles ahead are in the same lane. Since the systems are explicitly sold as *convenience* instead of *safety* systems, they only need to deal with normal situations with relatively low differences in velocity, and they leave the more difficult situations up to the human driver. The human is still alert, controlling the steering, and watching the traffic. These systems are being introduced by all the major car manufacturers.

62.4.3 Stop and Go

Stop-and-go driving assistance (also referred to as low-speed ACC) is at the opposite end of the speed spectrum, when vehicles creep along in dense traffic. At slow speeds, it is easy to track the vehicle ahead, and to move when it moves, steer when it steers, and stop when it stops. If the traffic accelerates to a modest speed, the stop-and-go system disengages, and the human must assume control of the throttle, brake, and steering. Since the speeds are very slow and the distances are short, many different sensing systems will work, such as stereo vision, radar, and lidar [62.86, 87].

62.4.4 Parking Assistance

Parking assistance is also a low-speed aid. In a typical scenario, the driver initiates the system by pushing a button when driving past an empty parking space. The system measures the length of the space using odometry, measures the positions of the cars in front and in back using short-range sensors, and infers the position of the curb by assuming that the surrounding cars are standard-sized cars parked near the curb [62.88]. Figure 62.18 illustrates parking assistance and fully automatic parking [62.88] (VIDEO 567).

Once the system is fully engaged, it takes over steering, planning, and executing the ideal parallel park steering sequence. In some systems, the human is still responsible for throttle and brake, again ensuring that the human is alert, watching for encroaching pedestrians or other obstacles. Such a system has been introduced by Toyota [62.89].

62.4.5 Lane Keeping

Lane keeping assistance is the natural extension to road departure warning systems. Given a lane tracking system, it is straightforward to add control of the steering wheel to keep the vehicle centered in its lane [62.4–6]. This has a number of uses. Some cities would like to run transit buses on narrow roadways, for instance the shoulder of highways or through narrow streets in old cities. Automated lane keeping systems using mechanical guideways are in use in several places [62.90]. It is easier and less expensive if such systems can be electronic rather than relying on specially installed mechanical guides. A specific subcategory is precision docking: for a transit bus to pick up a passenger in a wheelchair, either the bus must deploy a special ramp (which is a slow process), or it must pull up to a level dock and leave a very small gap, so that the wheel chair can safely roll on or off. Short-range precision docking systems use either a downward-looking sensor, looking at painted lines or magnetic markers, or a sideways sensor looking at the curb or dock, in order to guide the bus to its parking spot. Finally lane-keeping assistance is a convenience for driving on highways, especially with gusty winds. Honda has released a vehicle equipped with both lane-keeping assistance and adaptive cruise control (ACC) [62.91]. The danger with such systems is that the driver no longer has an active moment-to-moment role, and may lose concentration or even fall asleep. These systems are not designed for full automation, and still require a driver to handle unusual

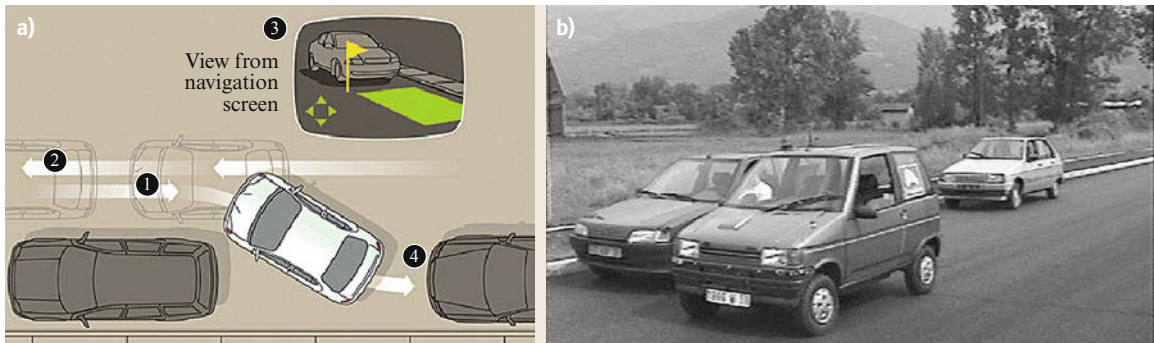

Fig.62.18a,b (a) Parking assistance and (b) fully automatic parking

circumstances. The next stage is to integrate driver state monitoring. If the driver is inattentive, then all automatic systems are disengaged.

62.4.6 Lane Changing

Lane changing assistance is the next extension in partial autonomy. It combines lane keeping and ACC with blind-spot monitoring. If the car can safely overtake a vehicle, then a lane change is undertaken and speed is unchanged [62.92]. Otherwise, the ACC slows the vehicle down. At its simplest, such a driver assistance system can advise a driver whether a lane change can be safely undertaken [62.93]. In its most advanced form the lane change is undertaken completely automatically

Fig. 62.19 Lane changing – side detection

by the vehicle [62.4]. Such systems require an additional side-facing sensor, typically radar (shown in Fig. 62.19)

62.5 Driver Monitoring

There has been an evolution of thought regarding the role of the driver in intelligent vehicles. The grand goal has been to replace the driver with a fully automated system. As discussed earlier, full automation of intelligent vehicles is still some years away due to system reliability and legal liability reasons. The next step in the development of motor vehicles is partial automation – where individual autonomous functions such as ACC, lane keeping, lane changing etc., are developed. Motor vehicle designers have realized that the driver cannot be removed from the vehicle and must instead be supported by systems onboard a motor vehicle. Over 92% of motor vehicle accidents are caused by driver error [62.94]. It is likely that the next generation of intelligent vehicles will work in the following way:

1. The vehicle will monitor the road scene using the advanced driver assistance system technologies discussed earlier to assess the state of the environment and warn the driver of dangerous situations, e.g., lane departure warnings.
2. The vehicle will also monitor the driver using vision and other physiological sensors to assess the state of the driver. If a driver is fatigued, drowsy, inattentive, distracted, under the influence of drugs, or has an emergency health condition such as heart attack, then accidents can occur. The vehicle warns the driver of dangerous circumstances, e.g., drowsiness warning.
3. For legal liability reasons, intelligent vehicles will not take control, rather the driver will be alerted using visual, audio, or tactile warnings. The vehicle will not perform collision avoidance; rather

collision mitigation will occur through emergency braking.

4. If an accident is unavoidable, the vehicle can autonomously apply emergency braking. To maximize the safety of the occupants in the vehicle, seat belt restraints are tightened and airbags are safely deployed.
5. After an accident has occurred, knowledge about the state of the driver and the passengers is important. If an occupant has been injured, a call to the emergency services can be dispatched automatically by the vehicle.

In all the steps described above monitoring the driver is critical. For future advanced driver assistance systems (ADAS) to work safely the driver should be put in the loop, for example, in lane departure warning systems, it is not possible to determine whether a vehicle departing from a lane is due to driver intention or error. If the state of the driver is being monitored, and the system can detect that the driver's eyes are closed or the driver is looking away from the road, then it can be inferred that the lane departure was involuntary and that a lane departure warning should be given to the driver. For ADAS to be accepted by drivers, the systems should not give false warnings. If the driver is looking directly at the road then lane departure warnings should not be given (or a different subtle warning should be given). Similarly more sophisticated systems, such as lane keeping, should not be engaged unless the driver is fully attentive and has his/her hands firmly on the steering wheel. The key point is that drivers must be fully engaged with and in control of the driving task.

This is a most important consideration in the design of **ADAS** for intelligent vehicles. A good overview of the challenges associated with putting drivers into **ADAS** systems is given in [62.95]

Combining perception with control gives partial automation for specific tasks, such as adaptive cruise control, lane keeping, assisted parking, and slow driving in stop-and-go situations.

62.5.1 Driver Fatigue, Inattention, and Impairment

By directly monitoring the driver using visual sensing opens up the possibility of developing a new class of **ADAS** applications. It is possible to monitor driver state through monitoring signals such as an electrocardiogram (ECG), temperature, etc. However, market studies by automobile manufacturers have shown that people do not like to have wires or gadgets attached; driver monitoring must be noncontact and noninvasive. The only solution is to use vision as the sensing medium. The technical challenge to develop a computer vision system that can automatically detect a driver of any age, sex, race, with/without eye or sunglasses, and with/without facial hair is enormous. Recently, significant progress was made with systems being developed that can also detect where a person is looking (gaze direction) [62.33, 96].

Once the driver's state (head position, eye gaze, eye blink rate) can be measured, then **ADAS** applications can be developed. Figure 62.20 shows the output of a commercial driver state detection system. See video for driver distraction, inattention and fatigue detection

 VIDEO 840

Driver Impairment

Safety authorities estimate that as many as 50% of all road accident fatalities are caused by driver impairment

Fig. 62.20 Driver state detection

due to alcohol or drugs [62.97]. Recent research has shown that driver impairment can be detected by sensing abnormal scanning patterns of eye gaze. It promises to open up a new class of **ADAS**. There have been major education and legislative initiatives in many Organization for Economic Cooperation and Development (OECD) countries, resulting in a significant reduction in road fatalities. However, the difficult cases (fatigue, distraction, and inattention) have become more prominent. **ADAS** technologies could have a significant impact in further reducing the road toll.

Driver Fatigue

Safety authorities estimate that 25–30% of all road fatalities are caused by driver fatigue [62.98, 99]. Research has shown that there are four visible factors that indicate the onset of fatigue – prolonged eye closure, uncontrolled head moments, drooping eyelids, and reduced eye-gaze scanning. Systems are under development that focus only on eye closure [62.100]; the challenge of fusing all four factors together into a robust algorithm that works for a wide range of drivers remains an open research problem.

Driver Inattention

Safety authorities estimate that up to 45% of all traffic accidents – from minor dents to serious incidents – are caused by driver inattention or distraction [62.101]. Research has shown that if the drivers consistently keep their eyes on the road, then driving becomes a much safer experience [62.102]. All major automotive manufacturers are developing **ADAS** applications that warn the driver if they are distracted from the driving task. More sophisticated **ADAS** under development use the driver's gaze direction to check whether safe driving practices are being followed, for example, did the driver check the side mirror before a lane change was performed? If the driver fails to check the side mirror a warning would be issued. Systems of this type have been demonstrated [62.103].

Driver Workload

The increase in new electronic systems and gadgets that are being installed into today's motor vehicles is also another source of distraction. Questions arise about when and under circumstances should a driver change a compact disc (CD) or answer a phone call. Research is underway into the development of workload systems. These systems take into account the vehicle state (speed, acceleration, braking, gear-change yaw rate, etc.) to determine whether information management tasks such as answering a phone call, sending a short message service (SMS) message are allowed [62.102]. The next stage of research is to include state infor-

mation about the road scene and the driver. If the car is driving on a country road, and the driver is attentive, then distractive tasks could be allowed and managed. Systems for monitoring the scene for monotony have been combined with fatigue detection systems – and can be combined with information management tasks [62.104]

62.5.2 Driver and Passenger Protection

The automotive industry is moving towards the use of active safety systems such as airbags to complement passive systems such as seat belts. ADAS will play a critical role in active safety systems. In emergency braking or impending rear-end collision situations, seat belts can be pretensioned and airbags primed. Drivers and passengers could be further protected through the development of smart airbags [62.105]. Airbags, while considered an essential part of a modern car, can cause fatalities if the occupant is too close to the airbag, is a child, or is not wearing a seat belt. Smart airbags are dependent on the position of the vehicle occu-

pant's head. The driver state monitoring technologies discussed earlier are an essential component of smart airbags.

62.5.3 Emergency Assistance

The speed at which people are given treatment after a serious accident is critically related to the survival rate of victims. While it is expected that ADAS will lead to a reduction in road accidents, it will not eliminate accidents. Therefore, it is important that automated systems for emergency situations are developed. Systems that use GPS, vehicle state information, and mobile communication systems have been developed that send the world coordinates of the vehicle to emergency authorities after an accident [62.106]. This information can be augmented by using driver monitoring technology to assess the condition of the occupants of the vehicle. Such types of system are referred to as Telematics are currently being tested by major automotive suppliers, including the development of aftermarket products [62.107].

62.6 Towards Fully Autonomous Vehicles

Intelligent vehicles that are fully autonomous can be justified for safety, traffic congestion, and environmental considerations.

62.6.1 Operating Safely

The first problem is safety. As stated earlier, automobile accidents are one of the main causes of human fatalities – on a staggering scale. This is a catastrophe of larger magnitude than all armed conflicts since the beginning of mankind. The most economically advanced countries (OECD) have been able to reduce the number of fatalities significantly through improved technology in vehicles – improved handling, braking, and passive safety. Transport infrastructure has been greatly improved; modern freeways are ten times safer than regular roads [62.108]. However, these improvements appear to be reaching a limit in terms of the number of deaths per million passengers-kilometers, particularly in industrialized countries.

As discussed earlier, motor vehicles are inherently dangerous due to their reliance on human control. Slight errors at high speeds can have catastrophic results. As discussed earlier the most common cause is driver distraction, which leads to improper reaction times or driving actions. Human error also frequently occurs while handling emergency situations. A large percentage of drivers will take improper action in such situations and

produce an accident that could have been avoided by a skilled and attentive driver [62.108]. The best solution to these problems is to remove the driver from the control loop. As discussed earlier, the interim step is to assist the driver to warn him/her in the case of potential danger (e.g., in the case of excessive speed before a dangerous bend or when a car is present in the blind spot while changing lane), or to take over control in emergency situations (e.g., emergency braking in the case of impending collision). For legal liability reasons, until it can be shown that autonomous systems have high integrity and reliability, people must be kept in the loop – in a supervisory capacity.

62.6.2 Traffic Congestion

The success of the automobile also leads to saturation of the road infrastructure, particularly in cities. Each car needs a certain amount of space in order to operate safely. The usual width of roads is 3.5 m in order to accommodate steering imprecision, while vehicles are about 2 m in width. Spacing between vehicles also has to be kept at a safe minimum to prevent collisions during deceleration (this principally depends on driver reaction time). It is usually recommended that the spacing should correspond to a time gap of at least 1.5 s. This spacing leads to a maximum throughput of about 2200 cars per hour per lane, independent of traf-

fic speed. This is not high if we consider that a suburban train can carry about 60 000 passengers per hour on an infrastructure of similar dimensions. Furthermore, high-density car traffic of greater than 2200 cars leads to a breakdown in traffic flow (stop-and-go traffic) and to an increased likelihood of accidents, which can drastically decrease the overall capacity of the system. The solution to this problem also lies in the removal of the driver from the control loop to improve lateral guidance (reduction of the width of lanes) and longitudinal control (with possible time gaps of around 0.3 s, independent of speed) while maintaining traffic safety. Such techniques of automated driving could multiply the throughput of road infrastructure by a factor of 5. This was demonstrated in particular by the work performed in the advanced highway systems (AHS) project in the USA, which led to the demonstration of seven-car platoons running at speeds up to 130 km/h on a dedicated freeway in San Diego with gaps of about 0.5 s [62.109].

Another congestion problem is associated with parking. Every individual vehicle is only used for a small percentage of its total usable life. Most of the time, motor vehicles occupy space very unproductively. Typically, a car requires about 10 m² of space. Usually, parking occurs at the curbside – a space that is very limited in large cities and cannot accommodate all cars of residents and visitors. In parking lots, each car will need four times this amount in order to have access to each individual slot. If a transportation system based on fully automated cars could be developed, people would not need to own cars but could rely on a service such as the one offered by taxis with vehicles that would come on demand and offer a complement to mass transport. This is the concept of the cybercar, which is under development in Europe [62.110].

62.6.3 Environmental Factors

The ever-increasing deployment of passenger and commercial vehicles has led to critical environmental problems of noise and of pollution in the local community. In addition greenhouse-gas emissions have an impact at the global environment level. Recently, automotive manufacturers have been able to reduce emissions of local pollutants drastically; noise in cities is now perceived as the major problem by the inhabitants. At the global level, the generation of CO₂ through the use of fossil fuels is also considered to be a major problem, which will require drastic steps. In the short term, this may lead to limiting the use of vehicles that generate CO₂ above certain levels. In the longer term, this will lead the automotive industry to offer vehicles that run on various forms of energy and to new forms of transportation systems with much higher efficiency. Au-

tomated vehicles running in platoon formations on new infrastructures could form such a system.

62.6.4 The Automobile of the Future

All three challenges are now at the heart of new policies being developed in many countries. These policies concern safety and emissions features in vehicles with a strong push towards advanced safety systems, as was recently seen in Europe with the *Intelligent Car Initiative* [62.111]. At the infrastructure level, there is also a strong push to implement regulation schemes to limit and control the use of road transport and promote alternative and more efficient transport means. In the future, this means that the use of a private automobile will be much more regulated and more integrated with other modes of transport.

The automotive industry might move from an industry of products to an industry of service where anyone can have access to mobility in the most cost efficient way. Both mass transportation and individual transportation would be offered by companies in the most cost-efficient way, respecting local regulations. Companies operating in this service industry could be transit operators, taxi companies, car rental companies, car-sharing companies or even new entrants into the transportation business such as mobile phone companies, which are already familiar with large customer bases and mobility services. Car-sharing operators such as those operating in Germany, Switzerland, Japan, and the USA are likely candidates [62.112]. Figure 62.21 shows a commercial car-sharing operation.

In this context, new types of vehicles such as electric ones and automated driving are being developed because of the decrease in the cost of operation and improvements in safety.

Demonstration projects by Honda and by Toyota have already been put in place along these lines. How-

Fig. 62.21 Car sharing at Toyota

ever, this market is still searching for its operators and business model, as well as the right products [62.110]. Figure 62.22 shows the Honda concept automated car.

There are two distinct trends in the future of automated vehicles. One is with advanced driving assistance, which has spread rapidly since the late 1990s with numerous techniques appearing recently in high-end passenger vehicles and commercial vehicles (buses and trucks). This trend was described earlier in this chapter. The other trend is associated with the arrival of people-movers based on automated guided vehicles (small or large) in specific locations and on dedicated tracks (protected or not).

It is forecast that, in the next 10 years, these two trends will merge, with individual vehicles having dual-mode capabilities: manual (with strong control and assistance) driving on regular roads and fully automatic driving on dedicated zones where no (or few) manual vehicles will be allowed, thereby ensuring smooth and safe operation of automated vehicles [62.110]. This type of vehicle will be perfect for the implementation of mobility services with vehicles that can be called on demand (perhaps through a mobile phone) when and where needed. With the development of such zones, new dedicated infrastructures will be built specifically for these vehicles to go automatically and at high speed from one automated zone to the next. This appears to be the most realistic path for *automated highways* to be realized, since it is now considered nearly impossible to have a smooth evolution from the actual infrastructure with its manual vehicles to one with a majority of fully automated ones. This is one of the reasons why the **AHS** project was canceled in the USA despite a very successful demonstration in 1997.

62.6.5 Automated Vehicle Deployment

As discussed earlier some automated functions are being introduced in production vehicles. Honda and

Fig. 62.22 Automated electric cars by Honda

Toyota have introduced a combination of lateral control (lane keeping assistance using image processing) and longitudinal control (adaptive cruise control using laser and radar sensors) [62.91]. An intelligent parking assist system was introduced recently by Toyota, offering the ability for the car to be parked without the driver using the steering wheel. However, this system does not use sensors: the driver has to position his/her vehicle on the image of the rear camera [62.89]. However, most car manufacturers and some component manufacturers are actively working on the sensors to remove this task from the driver.

Fully automated vehicles without any human intervention or supervision are now appearing in the commercial domain. Automated bus rapid transit (**ABRT**) combines the service quality of rail transit with the flexibility and cost of buses (as shown in Fig. 62.23). Nonautomated bus rapid transit (**BRT**) is already recommended by the World Bank in developing countries as the most efficient mass transport system. By reserving a dedicated lane for bus operation and adding some light infrastructure to facilitate loading and unloading, capacities similar to those of a train (60 000 passengers/h/direction) can be obtained, as has been demonstrated in South America [62.113]. By

Fig. 62.23 Toyota **ABRT** used in **IMTS** Phileas

Fig. 62.24 Cybercars at Schiphol airport, Amsterdam

adding the driving automation on a **BRT**, the system can be made more efficient and safer, as is already the case with automated metros.

The intelligent multimode transit system (**IMTS**) consists of vehicles guided by magnetic markers imbedded in the middle of their dedicated roads. The platoon running function (three electronically linked vehicles running in file formation at uniform speeds) of **IMTS** consists of precisely controlling the speed of all the vehicles in the platoon to be the same at all times [62.114]. In the city of Eindhoven in The Netherlands, multiarticulated buses with several steering axes also run in

automated mode on a dedicated track using magnetic markers [62.115]. These **ABRTs** usually keep a driver in the vehicle, since there is the possibility of reverting to manual mode if need be (such as for an unexpected obstacle or in situations with many pedestrians); however, future plans are for full automation.

ABRT technology can also be found with smaller vehicles, now called cybercars, for on-demand door-to-door operation [62.110]. These vehicles were put into operation for the first time at Schiphol airport (Amsterdam) in December 1997 to move passengers from long-term parking lots to the airport terminal (Fig. 62.24). Since then these cybercars have been further developed, financed by the Information Society Technologies (**IST**) program of the European Commission [62.110]. The long-term future of cybercars may lie with the development of dual-mode vehicles, with a particular emphasis on car-sharing operations [62.112]. Cybercars will have an automatic mode for operation in city centers (restricted to this type of vehicle) and a driver-operated (with assistance) mode for regular roads.  **VIDEO 429** illustrates the cybercar concept. The automobile industry is examining the viability of the development of such vehicles.

In order to match the performance of manually driven vehicles in urban environments, automated vehicles face major technical challenges. In particular, planning a trajectory for a car while avoiding moving and static obstacles remains as an important research challenge. In 2005, the **DARPA** Grand Challenge described at the beginning of this chapter brought together a large number of these researchers to demonstrate the feasibility of automated driving techniques. Five vehicles succeeded in completing the difficult course of 132 miles in the desert in totally autonomous mode. The 2007 **DARPA** challenge focused on multiple vehicles operating simultaneously in an urban environment; this challenge and the subsequent Google cars has certainly shown that automotive products based on autonomous vehicle techniques are becoming closer to market [62.15].

62.7 Future Trends and Prospects

Our cars, trucks, and buses are inevitably getting smarter. The future path is not completely known, and is likely to vary in different locations, but it is becoming widely accepted that there will be no need to drive our cars in the remote future. The time frame is still undefined, but it appears that autonomous cars will populate our highways – perhaps using special lanes– in less than a decade. Governments will not

only have to allow this change, but will have the great opportunity to influence its deployment, for example by increasing the number of dedicated lanes and the benefits that autonomous vehicles will obtain as opposed to less safe driving of manually driven cars.

Four different states in the USA have paved the way for having autonomous vehicles driven on regular

roadways (albeit for testing purposes), moving towards legislation that will make autonomous cars legal on everyday roads. This trend is not only happening in the USA, but also in Europe. Indeed, differences in culture and in driving habits will bring driverless technology into reality in selected locations earlier. Countries in which particularly fast and disrespectful driving is tolerated will make the introduction of autonomous vehicles challenging. Additionally, the safety issues associated with intermingling of autonomous and human driven cars have become critical and extensive investigations are again underway.

Several trends are clear, however. As sensor-equipped vehicles become more common, there will be increasing opportunities to build sensor-friendly technologies into roadways and into vehicles. It is straightforward to reduce the amount of radar clutter on road sides by replacing large metal signs, which are excellent radar reflectors, with nonreflective signs made of plastic or composites. At the same time, it will be desirable to increase the radar cross-section of small vehicles, such as motorcycles, to make them easier for radar-equipped cars to detect. Radar-reflecting licence plates, for in-

stance, would make smaller vehicles stand out more clearly.

The next steps may be to deploy systems that support the active transmission information from infrastructure to vehicle and vehicle to vehicle. Dedicated short-range communications (DSRC) is already in wide use in smart toll collection stations. It is easy to imagine DSRC-equipped vehicles receiving alerts from roadside sensors of upcoming fog, or ice, or congestion. Intelligent vehicles that detect unusual roadway conditions (via radar or lidar, slip detectors, or driver actions such as hard braking) could broadcast that information to all nearby smart vehicles. As market penetration of equipped vehicles increases, the value of such ad-hoc communications nets will go up dramatically.

Vehicle-to-vehicle communications need not be only via radio. Light-emitting diode (LED) brake lights can be pulsed at kilohertz frequencies, well above the bandwidth at which human eyes can detect flicker, but easily received by following vehicles. This would be a straightforward way for a vehicle to tell other vehicles about the onset of hard braking, or other unusual roadway conditions.

62.8 Conclusions and Further Reading

Advances in both the technologies and the algorithmic aspects of developing autonomous vehicles continue. Presently, impressive new systems have been demonstrated (Bertha [62.116] and PROUD [62.117]). In the first case, a Mercedes-Benz S 500 traveled on the historical route between Mannheim and Pforzheim in Germany in August 2013, while the PROUD experiment involved urban driving in open traffic in the inner city of Parma, Italy, and a part of the trip was made with nobody behind the steering wheel ( VIDEO 178).

The general public will become increasingly accustomed to intelligent systems – sensors and communications on vehicles. The only showstopper in the large-scale deployment of robotics technologies in the automobile field is the ability of the industry to deliver the technologies with total safety, which focuses attention on the problems of failsafe systems and their certification. The rail and aerospace industries have solved these problems but in a very different environment. In these industries, the cost of safety for each vehicle can be much higher than in a car or a bus, and the operational environment is also quite different, with professionals operating and maintaining the system. Manufacturers will slowly develop experience in reliability and cost engineering, and governments

will gradually work out liability issues. For these reasons, systems that put the driver in the loop of new automation technologies will be the current focus of development.

Many issues will need to be carefully addressed, including user acceptance, liability, and safety; however, it seems quite probable that this technology will lead to an unprecedented revolution in the field of transportation and people mobility.

63. Medical Robotics and Computer-Integrated Surgery

Russell H. Taylor, Arianna Menciassi, Gabor Fichtinger, Paolo Fiorini, Paolo Dario

The growth of medical robotics since the mid-1980s has been striking. From a few initial efforts in stereotactic brain surgery, orthopaedics, endoscopic surgery, microsurgery, and other areas, the field has expanded to include commercially marketed, clinically deployed systems, and a robust and exponentially expanding research community. This chapter will discuss some major themes and illustrate them with examples from current and past research. Further reading providing a more comprehensive review of this rapidly expanding field is suggested in Sect. 63.4.

Medical robots may be classified in many ways: by manipulator design (e.g., kinematics, actuation); by level of autonomy (e.g., preprogrammed versus teleoperation versus constrained cooperative control), by targeted anatomy or technique (e.g., cardiac, intravascular, percutaneous, laparoscopic, microsurgical); or intended operating environment (e.g., in-scanner, conventional operating room). In this chapter, we have chosen to focus on the role of medical robots within the context of larger computer-integrated systems including presurgical planning, intraoperative execution, and postoperative assessment and follow-up.

First, we introduce basic concepts of computer-integrated surgery, discuss critical factors affecting the eventual deployment and acceptance of medical robots, and introduce the basic system paradigms of surgical computer-assisted planning, execution, monitoring, and assessment (surgical CAD/CAM) and surgical assistance. In subsequent sections, we provide an overview of the technology of medical robot systems and discuss examples of our basic system paradigms, with brief additional discussion topics of remote telesurgery and robotic surgical simulators. We conclude with some thoughts on future research directions and provide suggested further reading.

63.1 Core Concepts

A fundamental property of robotic systems is their ability to couple complex information to physical action in order to perform a useful task. This ability to replace, supplement, or transcend human performance has had a profound influence on many fields of our society, including industrial production, exploration, quality control, and laboratory processes. Although robots have often been first introduced to automate or improve discrete processes such as welding or test probe placement or to provide access to environments where humans cannot safely go, their greater long-term impact has often come indirectly as essential enablers of computer integration of entire production or service processes.

63.1.1 Medical Robotics, Computer-Integrated Surgery, and Closed-Loop Interventions

Medical robots have a similar potential to fundamentally change surgery and interventional medicine as part of a broader, information-intensive environment that exploits the complementary strengths of humans and computer-based technology. The robots may be thought of as information-driven surgical tools that enable human surgeons to treat individual patients with greater safety, improved efficacy, and reduced morbidity than would otherwise be possible. Further, the consistency and information infrastructure associated with medical robotic and computer-assisted surgery systems have the potential to make *computer-integrated surgery* as important to health care as computer-integrated manufacturing is to industrial production.

Figure 63.1 illustrates this view of computer-integrated surgery (CIS). The process starts with infor-

mation about the patient, which can include medical images (computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), etc.), lab test results, and other information. This patient-specific information is combined with statistical information about human anatomy, physiology, and disease to produce a comprehensive computer representation of the patient, which can then be used to produce an optimized interventional plan. In the operating room, the preoperative patient model and plan must be *registered* to the actual patient. Typically, this is done by identifying corresponding landmarks or structures on the preoperative model and the patient, either by means of additional imaging (x-ray, ultrasound, video), by the use of a tracked pointing device, or by the robot itself. If the patient's anatomy has changed, then the model and plan are updated appropriately, and the planned procedure is carried out with assistance of the robot. As the intervention continues, additional imaging or other sensing is used to monitor the progress of the procedure, to update the patient model, and to verify that the planned procedure has been successfully executed. After the procedure is complete, further imaging, modeling, and computer-assisted assessment is performed for patient follow-up and to plan subsequent interventions, if any should be required. Further, all the patient-specific data generated during the planning, execution, and follow-up phases can be retained. These data can subsequently be analyzed statistically to improve the rules and methods used to plan future procedures.

63.1.2 Factors Affecting the Acceptance of Medical Robots

Medical robotics is ultimately an application-driven research field. Although the development of medical robotic systems requires significant innovation and can lead to very real, fundamental advances in technology, medical robots must provide measurable and significant advantages if they are to be widely accepted and deployed. The situation is complicated by the fact that these advantages are often difficult to measure, can take an extended period to assess, and may be of varying importance to different groups. Table 63.1 lists some of the more important factors that researchers contemplating the development of a new medical robot system should consider in assessing their proposed approach.

Broadly, the advantages offered by medical robots may be grouped into three areas. The first is the potential of a medical robot to *significantly improve surgeons' technical capability* to perform procedures by

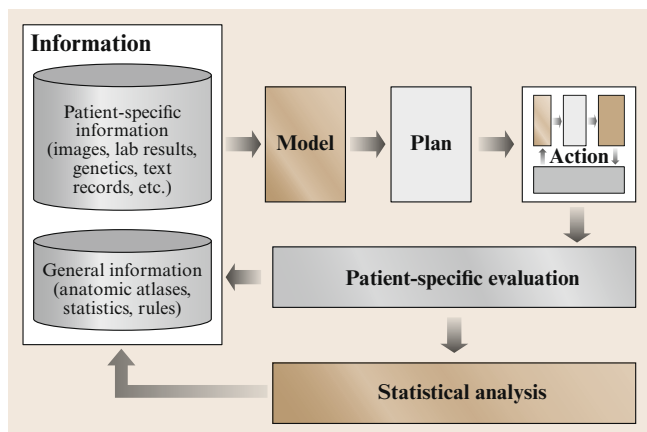

Fig. 63.1 Fundamental information flow in computer-integrated surgery

Table 63.1 Assessment factors for medical robots or computer-integrated surgery systems (after [63.1])

Assessment factor	Important to whom	Assessment method	Summary of key leverage
New treatment options	Clinical researchers, patients	Clinical and trials preclinical	Transcend human sensory-motor limits (e.g., in microsurgery). Enable less invasive procedures with real-time image feedback (e.g., fluoroscopic or MRI -guided liver or prostate therapy). Speed up clinical research through greater consistency and data gathering
Quality	Surgeons, patients	Clinician judgment; revision rates	Significantly improve the quality of surgical technique (e.g., in microvascular anastomosis), thus improving results and reducing the need for revision surgery
Time and cost	Surgeons, hospitals, insurers	Hours, hospital charges	Speed operating room (OR) time for some interventions. Reduce costs from healing time and revision surgery. Provide effective intervention to treat patient condition
Less invasiveness	Surgeons, patients	Qualitative judgment; recovery times	Provide crucial information and feedback needed to reduce the invasiveness of surgical procedures, thus reducing infection risk, recovery times, and costs (e.g., percutaneous spine surgery)
Safety	Surgeons, patients	Complication and revision surgery rates	Reduce surgical complications and errors, again lowering costs, improving outcomes and shortening hospital stays (e.g., robotic total hip replacement (THR), steady-hand brain surgery)
Real-time feedback	Surgeons	Qualitative assessment, quantitative comparison of plan to observation, revision surgery rates	Integrate preoperative models and intraoperative images to give surgeon timely and accurate information about the patient and intervention (e.g., fluoroscopic x-rays without surgeon exposure, percutaneous therapy in conventional MRI scanners). Assure that the planned intervention has in fact been accomplished
Accuracy or precision	Surgeons	Quantitative comparison of plan to actual	Significantly improve the accuracy of therapy dose pattern delivery and tissue manipulation tasks (e.g., solid organ therapy, microsurgery, robotic bone machining)
Enhanced documentation and follow-up	Surgeons, clinical researchers	Databases, anatomical atlases, images, and clinical observations	Exploit CIS systems' ability to log more varied and detailed information about each surgical case than is practical in conventional manual surgery. Over time, this ability, coupled with CIS systems' consistency, has the potential to significantly improve surgical practice and shorten research trials

exploiting the complementary strengths of humans and robots summarized in Table 63.2. Medical robots can be constructed to be more precise and geometrically accurate than an unaided human. They can operate in hostile radiological environments and can provide great dexterity for minimally invasive procedures inside the

patient's body. These capabilities can both enhance the ability of an *average* surgeon to perform procedures that only a few exceptionally gifted surgeons can perform unassisted and can also make it possible to perform interventions that would otherwise be completely infeasible.

Table 63.2 Complementary strengths of human surgeons and robots (after [63.1])

	Strengths	Limitations
Humans	Excellent judgment Excellent hand–eye coordination Excellent dexterity (at natural <i>human</i> scale) Able to integrate and act on multiple information sources Easily trained Versatile and able to improvise	Prone to fatigue and inattention Limited fine motion control due to tremor Limited manipulation ability and dexterity outside natural scale Cannot see through tissue Bulky end-effectors (hands) Limited geometric accuracy Hard to keep sterile Affected by radiation, infection
Robots	Excellent geometric accuracy Untiring and stable Immune to ionizing radiation Can be designed to operate at many different scales of motion and payload Able to integrate multiple sources of numerical and sensor data	Poor judgment Hard to adapt to new situations Limited dexterity Limited hand–eye coordination Limited haptic sensing (today) Limited ability to integrate and interpret complex information

A second, closely related capability is the potential of medical robots to *promote surgical safety* both by improving a surgeon’s technical performance and by means of active assists such as *no-fly zones* or *virtual fixtures* (Sect. 63.2.3) to prevent surgical instruments from causing unintentional damage to delicate structures. Furthermore, the integration of medical robots within the information infrastructure of a larger CIS system can provide the surgeon with significantly improved monitoring and online decision supports, thus further improving safety.

A third advantage is the inherent ability of medical robots and CIS systems to *promote consistency* while *capturing detailed online information* for every procedure. Consistent execution (e.g., in spacing and tensioning of sutures or in placing of components in joint reconstructions) is itself an important quality factor. If saved and routinely analyzed, the *flight data recorder* information inherently available with a medical robot can be used both in *morbidity and mortality* assessments of serious surgical incidents and, potentially, in statistical analyses examining many cases to develop better surgical plans. Furthermore, such data can provide valuable input for surgical simulators, as well as a database for developing skill assessment and certification tools for surgeons.

63.1.3 Medical Robotics System Paradigms: Surgical CAD/CAM and Surgical Assistance

We call the process of computer-assisted planning, registration, execution, monitoring, and assessment *surgical CAD/CAM*, emphasizing the analogy to manufacturing CAD/CAM. Just as in manufacturing, robots

can be critical in this CAD/CAM process by enhancing the surgeon’s ability to execute surgical plans. The specific role played by the robot depends somewhat on the application, but current systems tend to exploit the geometric accuracy of the robot and/or its ability to function concurrently with x-ray or other imaging devices. Typical examples include radiation therapy delivery robots such as Accuray’s CyberKnife [63.2] (Accuray, Inc., Sunnyvale, CA), shaping of bone in orthopaedic joint reconstructions (discussed further in Sect. 63.3.2) and image-guided placement of therapy needles (Sect. 63.3.3).

Surgery is often highly interactive; many decisions are made by the surgeon in the operating room and executed immediately, usually with direct visual or haptic feedback. Generally, the goal of surgical robotics is not to replace the surgeon so much as to improve his or her ability to treat the patient. The robot is thus a computer-controlled surgical tool in which control of the robot is often shared in one way or another between the human surgeon and a computer. We thus often speak of medical robots as *surgical assistants*.

Broadly, robotic surgical assistants may be broken into two subcategories. The first category, *surgeon extender robots*, manipulate surgical instruments under the direct control of the surgeon, usually through a teleoperation or *hands-on* cooperative control interface. The primary value of these systems is that they can overcome some of the perception and manipulation limitations of the surgeon. Examples include the ability to manipulate surgical instruments with superhuman precision by eliminating hand tremor, the ability to perform highly dexterous tasks inside the patient’s body, or the ability to perform surgery on a patient who is physically remote from the surgeon. Although setup time is still a serious concern with most surgeon extender

Fig. 63.2 The da Vinci telesurgical robot (after [63.3]) extends a surgeon's capabilities by providing the immediacy and dexterity of *open* surgery in a minimally invasive surgical environment (photos courtesy of Intuitive Surgical, Sunnyvale)

systems, the greater ease of manipulation that such systems offer has the potential to reduce operative times. One widely deployed example of a surgeon extender is the da Vinci system [63.3] (Intuitive Surgical Systems, Sunnyvale, CA) shown in Fig. 63.2. Other examples (among many) include the Sensei catheter system [63.7] (Hansen Medical Systems, Mountain View, CA.), the

Johns Hopkins University (JHU) *Steady Hand* micro-surgery robot [63.4–6] shown in Fig. 63.3 and discussed in Sect. 63.3, the Rio orthopaedic robot [63.8] (Mako Surgical Systems, Ft. Lauderdale, Florida), the DLR *Miro* system [63.9], the Surgica Robotica's *Sergenius* system (Surgica Robotica, Udine), and Titan Medical's *Amadeus* System (Titan Medical, Toronto, Canada).

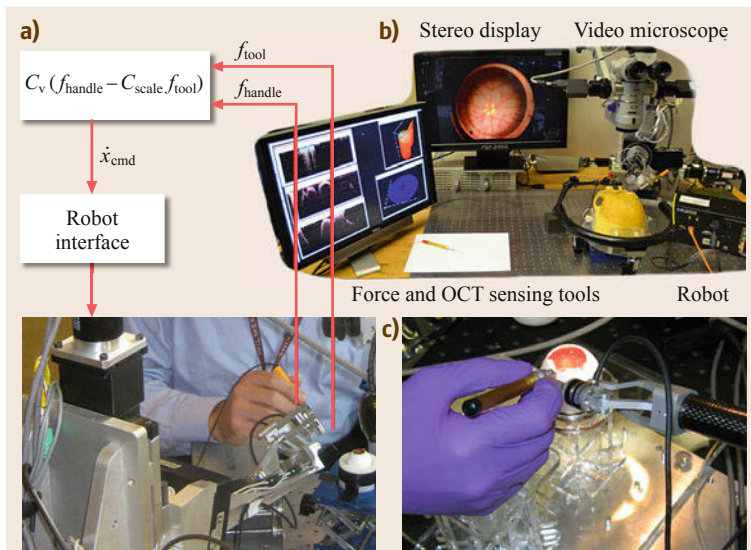

Fig. 63.3a–c The Johns Hopkins *Steady Hand* microsurgical robot (after [63.4–6]) extends a surgeon's capabilities by providing the ability to manipulate surgical instruments with very high precision while still exploiting the surgeon's natural hand-eye coordination. (a) The basic paradigm of hands-on compliant guiding. The commanded velocity of the robot is proportional to a scaled difference between the forces exerted by the surgeon on the tool handle and (optionally) sensed tool-to-tissue forces. (b) Current laboratory setup, showing the robot, stereo video microscope, stereo display with information overlays, display console for optical coherence tomography (OCT) system, and a sensorized tool. (c) An earlier recent version of the Steady Hand robot currently being used for experiments in microcannulation of 100 μ m blood vessels

A second category, *auxiliary surgical support robots*, generally work alongside the surgeon and perform such routine tasks as tissue retraction, limb positioning, or endoscope holding. One primary advantage of such systems is their potential to reduce the number of people required in the operating room, although that advantage can only be achieved if *all* the tasks routinely performed by an assisting individual can be automated. Other advantages can include improved task performance (e.g., a steadier endoscopic view), safety (e.g., elimination of excessive retraction forces), or simply giving the surgeon a greater feeling of control over the procedure. One of the key challenges in these sys-

tems is providing the required assistance without posing an undue burden on the surgeon's attention. A variety of control interfaces are common, including joysticks, head tracking, voice recognition systems, and visual tracking of the surgeon and surgical instruments, for example, the Aesop endoscope positioner [63.10] used both a foot-actuated joystick and a very effective voice recognition system. Again, further examples are discussed in Sect. 63.3.

It is important to realize that *surgical CAD/CAM* and *surgical assistance* are complementary concepts. They are not at all incompatible, and many systems have aspects of both.

63.2 Technology

The mechanical design of a surgical robot depends crucially on its intended application. For example, robots with high precision, stiffness and (possibly) limited dexterity are often very suitable for orthopaedic bone shaping or stereotactic needle placement, and medical robots for these applications [63.17–20] frequently have high gear ratios and consequently, low back-drivability, high stiffness, and low speed. On the other hand, robots for complex, minimally invasive surgery (MIS)

on soft tissues require compactness, dexterity, and responsiveness. These systems [63.3, 21] frequently have relatively high speed, low stiffness, and highly back-drivable mechanisms.

63.2.1 Mechanical Design Considerations

Many early medical robots [63.17, 20, 22] were essentially modified industrial robots. This approach has many advantages, including low cost, high reliability, and shortened development times. If suitable modifications are made to ensure safety and sterility, such systems can be very successful clinically [63.18], and they can also be invaluable for rapid prototyping and research use.

However, the specialized requirements of surgical applications have tended to encourage more specialized designs. For example, laparoscopic surgery and percutaneous needle placement procedures typically involve the passage or manipulation of instruments about a common entry point into the patient's body. There are three basic design approaches. The first approach uses a passive wrist to allow the instrument to pivot about the insertion point and has been used in the commercial Aesop and Zeus robots [63.21, 23] as well as several research systems. The second approach mechanically constrains the motion of the surgical tool to rotate about a *remote center of motion (RCM)* distal to the robot's structure. In surgery, the robot is positioned so that the RCM point coincides with the entry point into the patient's body. This approach has been used by the commercially developed da Vinci robot [63.3], as well as by numerous research groups, using a variety of kinematic designs [63.24–26]. Finally, a third approach uses an active external wrist [63.9, 17] and thus supports robot-assisted interventions that do not require a pivot point,

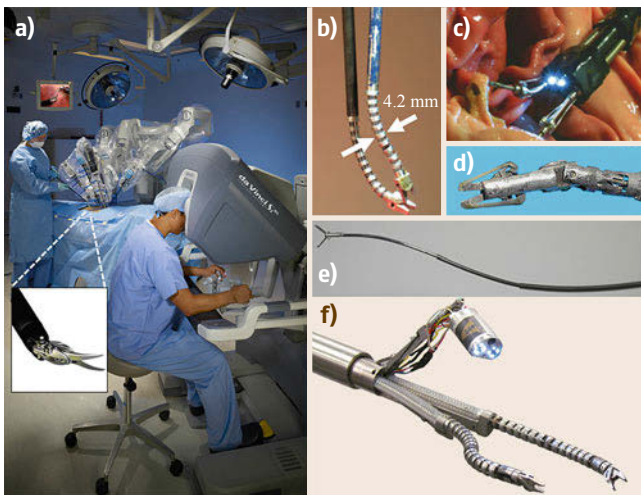

Fig. 63.4a–f Dexterity enhancement inside a patient's body: (a) The Intuitive da Vinci Si system and wrist with a typical surgical instrument (Photos courtesy of Intuitive Surgical) (after [63.3]); (b) The end-effectors of the JHU/Columbia snake telesurgical system (after [63.11]); (c) Two-handed manipulation system for use in endogastric surgery (after [63.12]); (d) five-degree-of-freedom 3 mm wrist and gripper (after [63.13]) for microsurgery in deep and narrow spaces; (e) concentric tube robot (after [63.14, 15]); (f) Columbia/Vanderbilt high dexterity system for single port access surgery (after [63.16])

potentially extending robotic surgery to other field of surgery.

The emergence of minimally invasive surgery has created a need for robotic systems that can provide high degrees of dexterity in very constrained spaces inside the patient's body, and at smaller and smaller scales. Figure 63.4 shows several typical examples of current approaches. One common response has been to develop cable-actuated wrists [63.3]. However, a number of investigators have investigated other approaches, including bending structural elements [63.11], shape-memory alloy actuators [63.27, 28], microhydraulic systems [63.29], and electroactive polymers [63.30]. Similarly, the problem of providing access to surgical sites inside the body has led several groups to develop semiautonomously moving robots for epicardial [63.31] or endoluminal applications [63.32, 33].

Two growing trends **MIS** are natural orifice trans-luminal surgery (**NOTES**) [63.34, 35] and single port laparoscopy (**SPL**) [63.36]: the idea is to get access to the abdominal cavity by using natural orifices and internal incisions (in **NOTES**) or existing human scars (e.g., the navel, in **SPL**). From the mechanical design viewpoint, there is the need to develop deployable surgical instruments or accessorised endoscopes and to combine flexibility (to reach the target) and stability of the platform (to achieve precision). Clashing of instruments and difficulty in triangulation are the main limitations which companies and research groups try to approach [63.37, 38].

The problem of distal operation, already present in **MIS**, is becoming more dramatic in **NOTES** and **SPL** and several solutions for helping surgical tasks requiring triangulation have been developed by different research groups [63.39]. They are based on magnetic fields which can generate an internal force without constraining the internal tool to the access port [63.40–42].

Another significant development in recent years has been the emergence and widespread deployment of three-dimensional (**3-D**) printing and other rapid prototyping technologies for clinically usable medical devices and medical robot components, as well as for construction of realistic patient-specific models [63.43, 44]. This trend has promoted very rapid progress in medical robot design and will be increasingly important in coming years.

Although most surgical robots are mounted to the surgical table, to the operating room ceiling, or to the floor, there has been growing interest in developing systems that directly attach to the patient [63.45, 46], and clinically deployed examples exist [63.47]. The main advantage of this approach is that the relative position of the robot and patient is unaffected if the patient moves. The challenges are that the robot must

be smaller and that relatively noninvasive means for mounting it must be developed.

Finally, robotic systems intended for use in specific imaging environments pose additional design challenges. First, there is the geometric constraint that the robot (or at least its end-effector) must fit within the scanner along with the patient. Second, the robot's mechanical structure and actuators must not interfere with the image formation process. In the case of x-ray and **CT**, satisfying these constraints is relatively straightforward. The constraints for **MRI** are more challenging [63.48].

63.2.2 Control Paradigms

Surgical robots assist surgeons in treating patients by moving surgical instruments, sensors, or other devices in relation to the patient. Generally, these motions are controlled by the surgeon in one of three ways:

- *Preprogrammed, semi-autonomous motion*: The desired behavior of the robot's tools is specified interactively by the surgeon, usually based on medical images. The computer fills in the details and obtains the surgeon's concurrence before the robot is moved. Examples include the selection of needle target and insertion points for percutaneous therapy and tool cutter paths for orthopaedic bone machining.
- *Teleoperator control*: The surgeon specifies the desired motions directly through a separate human interface device and the robot moves immediately. Examples include common telesurgery systems such as the da Vinci [63.3]. Although physical *master* manipulators are the most common input devices, other human interfaces are also used, notably voice control [63.21].
- *Hands-on compliant control*: The surgeon grasps the surgical tool held by the robot or a control handle on the robot's end-effector. A force sensor senses the direction that the surgeon wishes to move the tool and the computer moves the robot to comply. Early experiences with Robodoc [63.17] and other surgical robots [63.25] showed that surgeons found this form of control to be very convenient and natural for surgical tasks. Subsequently, a number of groups have exploited this idea for precise surgical tasks, notably the **JHU Steady Hand** microsurgical robot [63.4] shown in Fig. 63.3, the Rio orthopaedic robot [63.8] (Mako Surgical Systems, Ft. Lauderdale, Florida) and the Imperial College Acrobot orthopaedic system [63.49] shown in Fig. 63.5c,d.

These control modes are not mutually exclusive and are frequently mixed. For example, the Robodoc sys-

Fig. 63.5a–d Clinically deployed robots for orthopaedic surgery. **(a,b)** The Robodoc system (after [63.17, 18]) represents the first clinically applied robot for joint reconstruction surgery and has been used for both primary and revision hip replacement surgery as well as knee replacement surgery. **(c,d)** The Acrobot system of Davies et al. (after [63.49]) uses hands-on compliant guiding together with a form of virtual fixtures to prepare the femur and tibia for knee replacement surgery

tem [63.17, 18] uses hands-on control to position the robot close to the patient's femur or knee and preprogrammed motions for bone machining. Similarly, the IBM/JHU LARS robot, [63.25] used both cooperative and telerobotic control modes. The cooperatively controlled Acrobot [63.49] uses preprogrammed virtual fixtures (Sect. 63.1.3) derived from the implant shape and its planned position relative to medical images.

Each mode has advantages and limitations, depending on the task. Preprogrammed motions permit complex paths to be generated from relatively simple specifications of the specific task to be performed. They are most often encountered in surgical CAD/CAM applications where the planning uses two- (2-D) or three-dimensional (3-D) medical images. However, they can also provide useful complex motions combining sensory feedback in teleoperated or hands-on systems. Examples might include passing a suture or inserting a needle into a vessel after the surgeon has prepositioned the tip. On the other hand, interactive specification of motions based on real-time visual appreciation of deforming anatomy would be very difficult.

Teleoperated control provides the greatest versatility for interactive surgery applications, such as dexterous MIS [63.3, 21, 26, 50] or remote surgery [63.51, 52]. It permits motions to be scaled, and (in some research systems) facilitates haptic feedback between master and slave systems. The main drawbacks are complexity, cost, and disruption to standard operating room work flow associated with having separate master and slave robots.

Hands-on control combines the precision, strength, and tremor-free motion of robotic devices with some of the immediacy of freehand surgical manipulation. These systems tend to be less expensive than telesur-

gical systems, since there is less hardware, and they can be easier to introduce into existing surgical settings. They exploit a surgeon's natural eye–hand coordination in an intuitively appealing way, and they can be adapted to provide force scaling [63.4, 5]. Although direct motion scaling is not possible, the fact that the tool moves in the direction that the surgeon pulls it makes this limitation relatively unimportant when working with a surgical microscope. The biggest drawbacks are that hands-on control is inherently incompatible with any degree of remoteness between the surgeon and the surgical tool and that it is not practical to provide hands-on control of instruments with distal dexterity.

Teleoperation and hands-on control are both compatible with *shared control modes* in which the robot controller constrains or augments the motions specified by the surgeon, as discussed in Sect. 63.2.3.

63.2.3 Virtual Fixtures and Human–Machine Cooperative Systems

Although one goal of both teleoperation and hands-on control is often *transparency*, i. e., the ability to move an instrument with the freedom and dexterity he/she might expect with a handheld tool, the fact that a computer is actually controlling the robot's motion creates many more possibilities. The simplest is a safety barrier or *no-fly zone*, in which the robot's tool is constrained from entering certain portions of its workspace. More sophisticated versions include virtual springs, dampers, or complex kinematic constraints that help a surgeon align a tool, maintain a desired force, or maintain a desired anatomical relationship. The Acrobot system shown in Fig. 63.5c,d represents a successful clinical applica-

tion of the concept, which has many names, of which *virtual fixtures* seems to be the most popular [63.53, 54]. A number of groups are exploring extensions of the concept to active cooperative control, in which the surgeon and robot share or trade off control of the robot during a surgical task or subtask. As the ability of computers to model and follow along surgical tasks improves, these modes will become more and more important in surgical assistant applications. Figure 63.6 illustrates the overall concept of human-machine cooperative systems in surgery, and Fig. 63.7 illustrates the use of registered anatomical models to generate constraint-based virtual fixtures. These approaches are equally valid whether the surgeon interacts with the system through classical teleoperation or through hands-on compliant control. See also Chap. 43.

Both teleoperation and hands-on control are likewise used in human-machine cooperative systems for rehabilitation and disability assistance systems. Constrained hands-on systems offer special importance for rehabilitation applications and for helping people with movement disorders. Similarly, teleoperation and intelligent task following and control are likely to be vital for further advances in assistive systems for people with severe physical disabilities. See Chap. 64 for a further discussion of human-machine cooperation in assistive systems.

63.2.4 Safety and Sterility

Medical robots are safety-critical systems, and safety should be considered from the very beginning of the design process [63.55, 56]. Although there is some difference in detail, government regulatory bodies require a careful and rigorous development process with extensive documentation at all stages of design, implementation, testing, manufacturing, and field support. Generally, systems should have extensive redundancy built into hardware and control software, with multiple consistency conditions constantly enforced. The basic consideration is that no single point of failure should cause the robot to go out of control or to injure a patient. Although there is some difference of opinion as to the best way to make trade-offs, medical manipulators are usually equipped with redundant position encoders and ways to mechanically limit the speed and/or force that the robot can exert. If a consistency check failure is detected, two common approaches are to *freeze* robot motion or to cause the manipulator to go limp. Which is better depends strongly on the particular application.

Sterilizability and biocompatibility are also crucial considerations. Again, the details are application dependent. Common sterilization methods include gamma

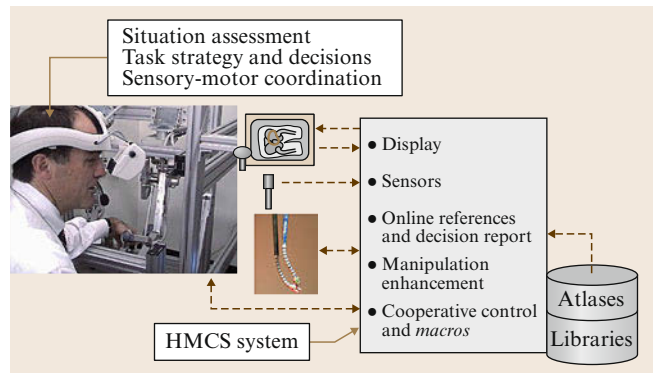

Fig. 63.6 Human-machine cooperative systems (HMCS) in surgery

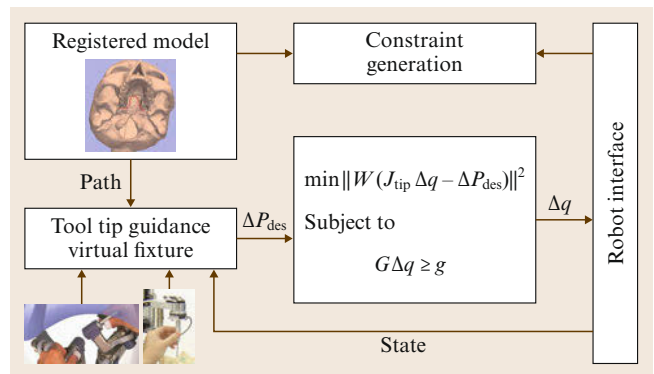

Fig. 63.7 Human-machine cooperative manipulation using constraint-based virtual fixtures, in which patient-specific constraints are derived from registered anatomical models (after [63.53])

rays (for disposable tools), autoclaving, soaking or gas sterilization, and the use of sterile drapes to cover unsterile components. Soaking or gas sterilization are less likely to damage robot components, but very rigorous cleaning is required to prevent extraneous foreign matter from shielding microbes from the sterilizing agent.

Careful attention to higher levels of application protocols is also essential. Just like any other tool, surgical robots must be used correctly by surgeons, and careful training is essential for safe practice. Surgeons must understand both the capabilities and limitations of the robot and of the surgical process as well, since safety is a systemic property. This adds new requirements to training programs, which must include robotic capabilities and nontechnical skills (Sect. 63.3.8). In surgical CAD/CAM applications, the surgeon must understand how the robot will execute the plan and be able to verify that the plan is being followed. If the surgeon is interactively commanding the robot, it is essential that the robot interpret these commands cor-

rectly. Similarly, it is essential that the robot's model of its task environment correspond correctly to the actual environment. The availability of task models is necessary to the development of autonomous execution of robotic gestures as well as the formal verification of task correctness [63.57]. Although careful design and implementation can practically eliminate the likelihood of a runaway condition by the manipulator, this will do little good if the robot is badly registered to the patient images used to control the procedure. If the robot fails for any reason, there must be well-documented and planned procedures for recovery (and possibly continuing the procedure manually).

Finally, it is important to remember that a well-designed robot system can actually *enhance* patient safety. The robot is not subject to fatigue or momentary lapses of attention. Its motions can be more precise and there is less chance that a slip of the scalpel may damage some delicate structure. In fact, the system can be programmed to provide *virtual fixtures* (Sect. 63.2.3) preventing a tool from entering a forbidden region unless the surgeon explicitly overrides the system.

63.2.5 Imaging and Modelling of Patients

As the capabilities of medical robots continue to evolve, the use of computer systems to model dynamically changing patient-specific anatomy will become increasingly important. There is a robust and diverse research community addressing a very broad range of research topics, including the creation of patient-specific models from medical images, techniques for updating these models based upon real-time image and other sensor data, and the use of these models for planning and monitoring of surgical procedures. Some of the pertinent research topics include the following:

- Medical image segmentation and image fusion to construct and update patient-specific anatomic models
- Biomechanical property measurement and modelling for analyzing and predicting tissue deformations and functional factors affecting surgical planning, control, and rehabilitation
- Optimization methods for treatment planning and interactive control of systems
- Methods for registering the *virtual reality* of images and computational models to the *physical reality* of an actual patient
- Methods for characterizing treatment plans and individual task steps such as suturing, needle insertion, or limb manipulation for purposes of planning, monitoring, control, and intelligent assistance

- Real-time data fusion for such purposes as updating models from intraoperative images
- Methods for human-machine communication, including real-time visualization of data models, natural language understanding, gesture recognition, etc.
- Methods for characterizing uncertainties in data, models, and systems and for using this information in developing robust planning and control methods.

An in-depth examination of this research is beyond the scope of this article. A more complete discussion of these topics may be found in the suggested further reading in Sect. 63.4.

63.2.6 Registration

Geometric relationships are fundamental in medical robotics, especially in surgical CAD/CAM. There is an extensive literature on techniques for coregistering coordinate systems associated with robots, sensors, images, and the patient [63.58, 59]. Following [63.59], we briefly summarize the main concepts here. Suppose that we have coordinates

$$\mathbf{v}_A^r = (x_A, y_A, z_A)$$

$$\mathbf{v}_B^r = (x_B, y_B, z_B),$$

corresponding to comparable locations in two coordinate systems Ref_A and Ref_B . Then the process of registration is simply that of finding a function $T_{AB}(\cdots)$ such that

$$\mathbf{v}_B = T_{AB}(\mathbf{v}_A).$$

Generally, $T_{AB}(\cdots)$ is assumed to be a rigid transformation of the form

$$T_{AB}(\mathbf{v}_A^r) = \mathbf{R}_{AB}\mathbf{v}_A^r + \mathbf{p}_{AB},$$

where \mathbf{R}_{AB} represents a rotation and \mathbf{p}_{AB} represents a translation, but nonrigid transformations are becoming increasingly common. There are hundreds of methods for computing $T_{AB}(\cdots)$. The most common for medical robotics involve finding a set of corresponding geometric features Γ_A and Γ_B whose coordinates can be determined in both coordinate systems and then finding a transformation that minimizes some distance function $d_{AB} = \text{distance}[\Gamma_B, T_{AB}(\Gamma_A)]$. Typical features can include artificial fiducial objects (pins, implanted spheres, rods, etc.) or anatomical features such as point landmarks, ridge curves, or surfaces.

One common class of methods is based on the iterated closest-point algorithm of *Besl* and *McKay* [63.60],

for example, 3-D robot coordinates a_j may be found for a collection of points known to be on the surface of an anatomical structure that can also be found in a segmented 3-D image. Given an estimate T_k of the transformation between image and robot coordinates, the method iteratively finds corresponding points b_j on the surface that are closest to $T_k a_j$ and then finds a new

transformation

$$T_{k+1} = \arg \min_T \sum_j (b_j - T a_j)^2.$$

The process is repeated until some suitable termination condition is reached.

63.3 Systems, Research Areas, and Applications

Medical robots are not ends in themselves. As the late Hap Paul often remarked, *the robot is a surgical tool designed to improve the efficacy of a procedure*. (Paul was the founder of Integrated Surgical Systems. Along with William Bargar, he was one of the first people to recognize the potential of robots to fundamentally improve the precision of orthopaedic surgery.)

63.3.1 Nonrobotic Computer-Assisted Surgery: Navigation and Image Overlay Devices

In cases where the role of the robot is placing instruments on targets determined from medical images, *surgical navigation* is often a superior alternative. In surgical navigation [63.61], the positions of instruments relative to the reference markers on the patient are tracked using specialized electromechanical, optical, electromagnetic, or sonic digitizers or by more general computer vision techniques. After the relationships between key coordinate systems (patient anatomy, images, surgical tools, etc.) are determined through a registration process (Sect. 63.2.6), a computer workstation provides graphical feedback to the surgeon to assist in performing the planned task, usually by displaying instrument positions relative to medical images, as shown in Fig. 63.8a. Although the registration is usually performed computationally, a simple mechanical alignment of an image display with an imaging device can be surprisingly effective in some cases. One example [63.62] is shown in Fig. 63.8b.

The main advantages of surgical navigation systems are their versatility, their relative simplicity, and their ability to exploit the surgeon's natural dexterity and haptic sensitivity. They are readily combined with *passive* fixtures and manipulation aids [63.65, 66]. The main drawbacks, compared to active robots, are those associated with human limitations in accuracy, strength, ability to work in certain imaging environments, and dexterity inside the patient's body (Table 63.2).

Because these advantages often outweigh the limitations, surgical navigation systems are achieving

widespread and increasing acceptance in such fields as neurosurgery, otolaryngology, and orthopaedics. Since much of the technology of these systems is compatible with surgical robots and since technical problems such as registration are common among all these systems, we may expect to see a growing number of hybrid applications combining medical robots and navigation.

63.3.2 Orthopaedic Systems

Orthopaedic surgery represents a natural surgical CAD/CAM application, and both surgical navigation systems and medical robots have been applied to orthopaedics. Bone is rigid and is easily imaged in CT and intraoperative x-rays, and surgeons are accustomed to doing at least some preplanning based on these images. Geometric accuracy in executing surgical plans is very important, for example, bones must be shaped accurately to ensure proper fit and positioning of components in joint replacement surgery. Similarly, osteotomies require both accurate cutting and placement of bone fragments. Spine surgery often requires screws and other hardware to be placed into vertebrae without damage to the spinal cord, nerves, and nearby blood vessels.

The Robodoc system shown in Fig. 63.5a,b represents the first clinically applied robot for joint reconstruction surgery [63.17, 18]. Since 1992, it has been applied successfully to both primary and revision hip replacement surgery, as well as knee surgery. Since this system exhibits many of the characteristics of surgical CAD/CAM, we will discuss it in some detail. In the *surgical CAD* phase, the surgeon selects the desired based on preoperative CT images and interactively specifies the desired position of the implant components. In the *surgical CAM* phase, surgery proceeds normally up to the point where the patient's bones are to be prepared to receive the implant. The robot is moved up to the operating table, the patient's bones are attached rigidly to the robot's base, and the robot is registered to the CT images either by use of implanted fiducial pins or by use of a 3-D digitizer to match bone

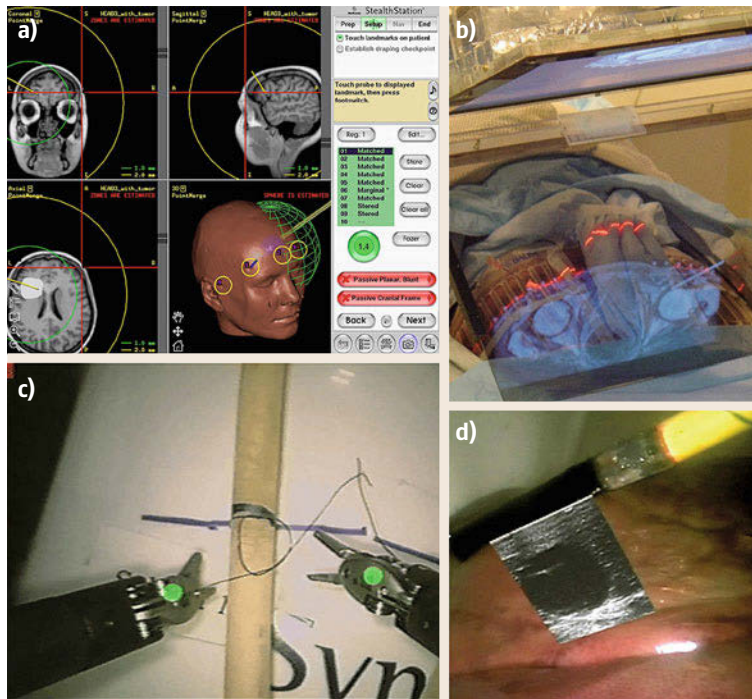

Fig.63.8a–d Information enhancement for surgical assistance. (a) Display from a typical surgical navigation system, here the Medtronic StealthStation; (b) the JHU image overlay system (after [63.62]) uses a mirror to align the virtual image of a cross-sectional image with the corresponding physical position in the patient's body; (c) Sensory substitution display of surgical force information onto da Vinci surgical robot video monitor (after [63.63]); (d) Overlay of laparoscopic ultrasound onto the da Vinci surgical robot video monitor (after [63.64])

surfaces to the CT images. After registration, the surgeon's hand guides the robot to an approximate initial starting position. Then, the robot autonomously machines the desired shape with a high-speed rotary cutter while the surgeon monitors progress. During cutting, the robot monitors cutting forces, bone motion, and other safety sensor, and either the robot controller or the surgeon can pause execution at any time. If the procedure is paused for any reason, there are a number of error recovery procedures available to permit the procedure to be resumed or restarted at one of several defined checkpoints. Once the desired shape has been machined, surgery proceeds manually in the normal manner.

Subsequently, several other robotic systems for joint replacement surgery have been introduced or proposed. The references in Sect. 63.4 provide numerous examples. Notable hands-on guided systems include Rio surgical robot [63.8] (Mako Surgical, Ft. Lauderdale, Florida) and the Acrobot [63.49] system for knee surgery shown in Figs. 63.5c,d. Similarly, several groups have recently proposed small orthopaedic robots attaching directly to the patient's bones [63.45] or completely freehand systems such as the NaviPFS surgical system (Blue Belt Technologies, Pittsburgh, Pa.) which combine surgical navigation with very fast on-off control of a surgical cutter [63.67, 68]. A recent example of a hybrid passive-active robot is [63.69].

63.3.3 Percutaneous Needle Placement Systems

Needle placement procedures have become ubiquitous in image-guided intervention, typically performed through the skin but also through cavities. These procedures fit within the broader paradigm of surgical CAD/CAM, where the process involves use of patient images to identify targets within the patient and planning needle trajectories; inserting the needles and verifying their placement; performing some action such as an injection or taking a biopsy sample; and assessing the results. In most cases, an accuracy of 1–2 mm is acceptable, which is not easy to achieve freehand, because the target is not directly visible, soft tissues tend to deform and deflect, and needles often bend. The procedures typically rely on some form of intra-operative imaging (x-ray, CT, MRI, and ultrasound) for both guidance and verification. The surgical motion sequence typically has three decoupled phases: place the needle tip at the entry point, orient the needle by pivoting around the needle tip, and insert the needle into the body along a straight trajectory. These motions are often performed freehand, with varying degrees of information feedback for the physician. However, passive, semiautonomous, and active robotic systems have all been introduced. Figure 63.9 shows several clinically deployed systems for needle placement.

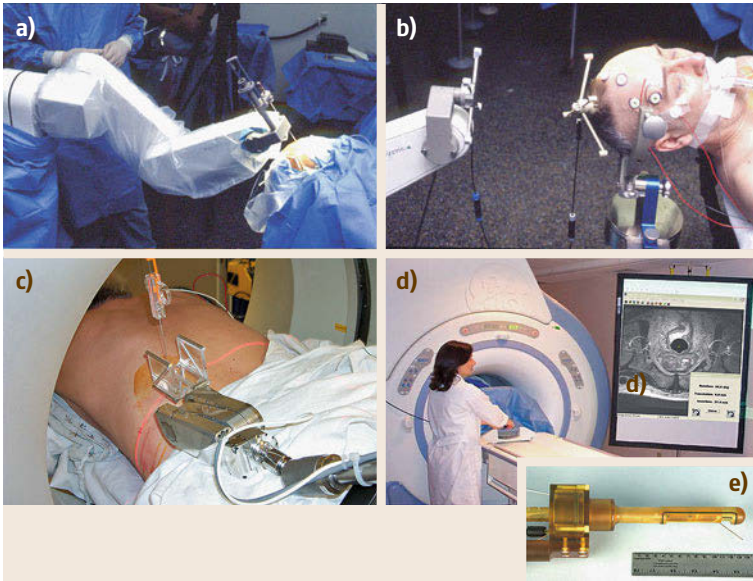

Fig.63.9a–e Clinically deployed systems for in-scanner needle placement. **(a,b)** The Neuromate system (after [63.19]) for stereotactic procedures in the brain uses a novel noncontact sensing system for robot-to-image registration; **(c)** Johns Hopkins system for in-CT needle placement (after [63.70, 71]); **(d,e)** Manually activated device for in-MRI transrectal needle placement into the prostate (after [63.72])

Freehand Needle Placement Systems

Freehand needle placement with **CT** and **MRI** guidance uses skin markers to locate the entry point [63.62], reference to the scanner's alignment laser to control needle direction, and markers on the needle to control depth. With ultrasound, the primary reliance is on surgeon experience or the use of some sort of needle guide to drive the needle to target while it passes in the ultrasound plane. Tracked ultrasound snapshots guidance combines orthogonal viewpoints with frozen ultrasound image frames [63.73]. Mechanical needle guides [63.61], hand-held navigation guidance [63.74], and optical guides have been combined with most imaging modalities. These include laser guidance devices [63.75], augmented reality systems [63.76]. Augmented reality with 2-D ultrasound [63.77] and **CT/MRI slices** [63.62] (Fig. 63.8b) was developed, where a semi-transparent mirror is used together with a flat-panel display to create the appearance of a virtual image floating inside the body in the correct position and size.

Passive and Semiautonomous Devices for Needle Placement

Passive, encoded manipulator arms were proposed for image-guided needle placement [63.78], where following a registration step, the position and orientation of a passive needle guide is tracked and the corresponding needle path is displayed on **CT** or **MRI** images. Semiautonomous systems allow remote, interactive image-guided placement of needles, such as transrectal prostate needle placement in **MRI** environment [63.72] with an actuated manipulator from outside

the scanner bore, while the needle driver is tracked in **MRI** with active coils.

Active Robots for Needle Placement

Neurosurgery was one of the first clinical applications of active robots [63.19, 20, 22], a natural application for surgical **CAD/CAM**. The entry and target points are planned on **CT/MRI** images, the robot coordinate system is registered to the image coordinate system (typically with markers affixed to the patient's head), and then the robot positions a needle or drill guide. The marker structure may be a conventional stereotactic head frame or, as in the Neuromate system [63.19], registration is achieved by simultaneous tracking of the robot and markers attached to the patient's skull. Spatial constraints in needle placement led to the development of structures achieving *remote center of motion* (**RCM**) or fulcrum motion [63.24, 25]. In these systems, the **RCM** is positioned at the entry point, typically with an active Cartesian stage or a passive adjustable arm, and the robot sets the needle direction and (sometimes) the depth. To speed up imaging, planning, registration, and execution, the robot can work concurrently with imaging devices, such as variants of an **RCM**-based system that was deployed with x-ray [63.24] and **CT** guidance [63.70, 71]. In [63.71], a marker structure was incorporated in the needle driver to register the robot with a single image slice. **MRI** has an excellent potential for guiding, monitoring, and controlling therapy, invoking intensive research on **MRI**-compatible robotic systems for needle placement [63.79] and other more interactive procedures [63.50]. Ultrasound guid-

ance offers many unique advantages: is relatively inexpensive and compact, provides real-time images, does not involve any ionizing radiation, and does not impose significant materials constraints on the robot design. Several robotic systems have been proposed for prostate interventions [63.80] using transrectal ultrasound guidance. For other ultrasound-guided needle placement applications, examples include experimental systems for liver [63.64, 81], gallbladder [63.82], and breast [63.83]. Figure 63.8d shows one example of the use of information overlay to assist in needle placement in a telesurgical application [63.64]. Whatever form of image feedback is available, steering flexible needles to hit desired targets while avoiding obstacles is a ubiquitous problem, having led to several novel approaches [63.84, 85] and reviewed most recently in [63.86]. Concentric tube robots (also interchangeably called *active cannulas* due to their usefulness in medicine), consist of several precurved elastic tubes nested within one another. Actuators grasp these tubes at their bases and extend them telescopically while also applying axial rotations. These movements cause the overall device to elongate and bend, providing a needle-sized device that moves in a manner analogous to a tentacle. Chronologically, a precursor to current concentric tube robots was an early steerable needle design where a curved stylet was used at the tip of a needle to induce steering [63.87]. These robots fall within the broader class of continuously flexible robots called *continuum robots* (see [63.15] for a review.) Over the past few years, mechanics-based models of active cannulas have rapidly matured due to the simultaneous parallel efforts of several research groups [63.14, 88]. Today, these models provide the basis for an active subfield of research on teleoperative control, surgery-specific design, and motion planning research. Surgical applications suggested for concentric tube robots and are in various stages of development, ranging from purely conceptual to animal studies, which will make the next several years exciting for translational clinical research.

63.3.4 Telesurgical Systems

The concepts of telemedicine, telesurgery, and telepresence in surgery date from the 1970s. Since then, the potential for telesurgical systems to facilitate effective interventions in remote or hostile environments such as the battlefield, space, or thinly populated areas has continued to be recognized [63.89], and there have been some spectacular demonstrations including a transatlantic cholecystectomy [63.51] in 2001, experiments in Italy [63.90] and Japan [63.91] as well as more nearly routine use in Canada [63.52]. The oper-

ational difficulties due to the intrinsic communication delay of long distance tele-surgery affect usability and safety and make the regular use of tele-surgery quite uncommon.

However, the primary uses of telesurgical systems have been with the surgeon and patient in the same operating room. Teleoperated robots have been used for over 15 years in MIS, both as auxiliary surgical support systems to hold endoscopes or retractors [63.23, 25, 92–94] and as *surgeon extender* systems to manipulate surgical instruments [63.3, 26]. There has also been recent work to develop telesurgical systems for use within imaging environments such as MRI [63.95].

A primary challenge for auxiliary support systems is to permit the surgeon to command the robot while his or her hands are otherwise occupied. Typical approaches have included conventional foot switches [63.23], instrument-mounted joysticks [63.25], voice control [63.10, 25], and computer vision [63.25, 96, 97].

A common goal in surgeon extender systems is to provide a measure of telepresence to the surgeon, specifically, to give the surgeon the sensation of performing open surgery from inside the patient. In early work, Green et al. [63.98] developed a successful prototype system for telesurgery combining remote manipulation, force feedback, stereoscopic imaging, ergonomic design, etc. Subsequently, several commercial telesurgical systems have been applied clinically for MIS. Of these, Intuitive Surgical's da Vinci [63.3] has been the most successful, with over 2500 systems deployed as of 2013. Experience with these systems has demonstrated that a high-dexterity wrist is often critical for surgeon acceptance. Although originally targeted at cardiac surgery, as well as more general interventions, the most successful clinical applications to date are radical prostatectomies, where significant improvements in outcomes have been reported [63.99], and hysterectomy, where the clinical benefits compared to conventional laparoscopy are still being studied [63.100].

One emerging area for research exploits the inherent ability of telesurgical systems to act as *flight data recorders* during surgical procedures. Several authors [63.101–104] have begun analyzing such data for such purposes as measuring surgical skill, learning surgical gestures and motions, and providing data for surgical simulators. Another emerging area for research [63.105] focuses on semi-automation of surgical gestures between the surgeon and the robot, often based on learned models. Other research [63.106–108] exploits augmented reality methods to enhance the information available to the surgeon during telesurgical procedures.

63.3.5 Microsurgery Systems

Although *microsurgery* is not a consistently defined term, it generally indicates procedures performed on very small, delicate structures, such as those found in the eye, brain, spinal cord, small blood vessels, nerves, or the like. Microsurgical procedures are commonly performed under direct or video visualization, using some form of magnification (e.g., microscope, surgical loupes, high-magnification endoscope). The surgeon typically has little or no tactile appreciation of the forces being exerted by the surgical instruments and physiological hand tremor can be a significant factor limiting surgical performance. Robotic systems can help overcome these human sensory-motor limitations, and efforts to develop specialized systems for applications such as ophthalmology [63.6, 109–115] and otology [63.116–118]. Several groups have also experimented with magnetic manipulation for these applications [63.113, 119]. There have been several efforts to compare microsurgical anastomosis procedures using laparoscopic telesurgical systems to conventional microsurgery. Schiff et al. [63.120] among others reported significant reductions in tremor with either robot and significantly improved technical quality and operative times compared to conventional microsurgery. As the number of da Vinci systems has proliferated, such applications are increasingly common [63.121]. A number of groups have implemented telesurgery systems specifically for microsurgery [63.13, 122–124] [63.95, 109]. These systems are in various stages of development, from laboratory prototype to preliminary clinical experimentation.

Not all microsurgical robots are teleoperated. For example, the cooperatively controlled JHU Steady Hand robots [63.4, 5] [63.6, 115] shown in Fig. 63.3 are being developed for retinal, head-and-neck, neurosurgery, and other microsurgical applications. A modified version of this system has also been used for microinjections into single mouse embryos [63.125].

There have also been efforts to develop completely hand-held instruments that actively cancel physiological tremor, for example, Riviere et al. [63.126–128] have developed an ophthalmic instrument using optical sensors to sense handle motion and adaptive filtering to estimate the tremulous component of instrument motion. A micromanipulator built into the instrument deflects the tip with an equal but opposite motion, compensating the tremor. Simple mechanical devices [63.129] for reducing tremor in specific tasks have also been developed.

An additional type of hand-held microsurgical and micro-therapeutic devices is reported in [63.130], which describes an active microendoscope for neuroen-

doscopy and therapy of the spinal cord able to safely navigate in the subarachnoid space and to avoid dangerous contact with the internal delicate structures thanks to a system based on hydrojets. Hydrojets come from the lateral surface of the catheter and, appropriately tuned and oriented, allow the tip of the endoscope to proceed without touching the spinal cord internal walls. The shared control system of the neuroendoscope, based on processing, segmentation, and analysis of the endoscopic images, assists the safe advancement of the tool in real time [63.131].

63.3.6 Endoluminal Robots

The term *endoluminal surgery* was first coined by Cuschieri et al. [63.132] as a major component of endoscopic surgery. Endoluminal procedures consist of bringing a set of advanced therapeutic and surgical tools to the area of interest by navigating in the lumina (i.e., the tube-like structures) of the human body, such as the gastrointestinal (GI) tract, the urinary tract, the circulatory system, etc. Currently, most endoluminal robots are designed for gastrointestinal applications, although there has been some initial work for other areas. There are several advantages (from a robotics research perspective) of working in the GI tract. The GI tract is not sterile and relatively large in diameter. Further it can be punctured intentionally to reach other abdominal cavities in NOTES approaches.

Traditionally, catheters and flexible endoscopes for endoluminal procedures have been inserted and manipulated manually from outside the body with the assistance of one or more visualization systems (e.g., direct endoscopic video, x-ray fluoroscopy, ultrasound). One major challenge is limited dexterity making it difficult to reach the desired target. Typically, flexible endoscopes have a bendable tip that can be steered by means of cable drives, and catheters may have only a fixed bend on a guide wire. There is also the inherent difficulty of *pushing a rope*, which some companies are trying to address by using external magnetic field (e.g., [63.133]). Once the target site is reached, these limitations become even more significant. Very simple instruments can be inserted through working channels or slid over guide wires, but dexterity is severely limited and there is no force feedback beyond what can be felt through the long, flexible instrument shaft.

These limitations have led a number of researchers to explore integration of more degrees of freedom in the catheter/endoscope body, as well as the design of intelligent tips with higher dexterity and sensing capabilities. Early work by Ikuta et al. led to the development of a five-segment, 13 mm-diameter sigmoidoscope using shape-memory alloy (SMA) actuators.

Subsequently, *Ikuta et al.* developed 3 mm-diameter active endovascular devices using hydraulic actuators incorporating a novel band pass valve fabricated using micro-stereolithographic techniques [63.29].

Several examples exist of instrumented catheter tips with force sensors [63.134] that allow the right branch of the circulatory systems to be found by estimating the force generated between the tip and the vessel walls. Basically, these sensorized endoluminal devices belong to the larger group of micro-electromechanical systems (MEMS)-instrumented surgical devices and the same sensing technologies can be also exploited for microsurgery. A survey article by *Rebello* [63.135] provides an excellent overview of sensorized catheters and other MEMS-based devices in endoluminal and microsurgical applications.

Another approach to endoluminal robots is represented by systems that move under their own power through the body, rather than being pushed. Early work on such systems is well summarized in [63.136]. In 1995 *Burdick et al.* developed an inchworm-like mechanism for use in the colon. This device combined a central extensor for propulsion and inflatable balloons for friction enhancement with the slippery colon tissue. A more advanced inchworm design for a semi-autonomous robotic colonoscope was developed by *Dario et al.* [63.33] (Fig. 63.10). This device consists of a central silicone elongator, two clamping systems based on suction and gentle mechanical grasping of the colon tissue, and a silicone steerable tip integrating a complementary metal-oxide-semiconductor (CMOS) camera and a light-emitting diode (LED)-based illumination system. Thanks to its intrinsic flexibility, the robotic colonoscope applies forces on colon tissues that are ten times lower than those produced by traditional colonoscopies. This system is now clinically tested [63.137], and similar devices combining flexibility and painless operation have been proposed by some companies [63.138, 139]. Although the application is not endoluminal, the HeartLander system of *Riviere et al.* [63.31] shown in Fig. 63.11a,b shares many of the characteristics of these systems. It uses an inchworm-like gait to traverse the surface of the heart and to perform simple operation. An instructive paper on the combination between flexibility and stiffness of endoscopic devices for allowing painless manoeuvrability and stable anchoring when performing surgical tasks has been recently published [63.140]. It presents a number of design criteria and solutions for transforming endoscopic devices from diagnostic tools to stable surgical platforms.

The natural evolution of GI endoscopic devices is represented by endoscopic capsules [63.141] which keep the promise to make endoscopy of the GI tract

Fig.63.10a,b Medical robot for colonoscopy (after [63.33]): (a) the *gait* cycle of the robot, consisting of: (1) proximal clamping, (2) elongation, (3) distal clamping, and (4) retraction; (b) a recent working prototype used for clinical trials

a screening method highly tolerated by patients. For transforming simple CMOS swallowable cameras with illumination and transmission functionalities into useful diagnostic devices, several research groups have explored variegated solutions for active capsule locomotions. An example of legged locomotion capsules for GI application is illustrated in Fig. 63.11c and described in [63.28, 142]. In order to overcome dramatic powering problems, magnetic capsules propelled by permanent magnets [63.143] or by modified MRI fields [63.144] have been proposed. An earlier application of electromagnetic manipulation of an object within the body was the *video tumor fighter* of *Ritter et al.* [63.145].

63.3.7 Sensorized Instruments and Haptic Feedback

Surgical procedures almost always involve some form of physical interaction between surgical instruments

and patient anatomy, and surgeons are accustomed to use their haptic appreciation of tool-to-tissue interaction forces in performing surgical procedures. In situations such as where the clumsiness of instrumentation or human sensory-motor limitations limit the surgeon's ability to feel these forces, surgeons have been trained to rely on visual or other cues to compensate. Apart from the need for haptic feedback for diagnostic procedures and tissue identification, it has been demonstrated that reduced tactile and force information can result in the application of unnecessarily large forces on the patient during surgery, with possible harm to the patient [63.146]. The quality of haptic feedback available in currently deployed surgical robots is poor or nonexistent. Current research addresses the limitations firstly by integrating force and other sensors into surgical end-effectors and secondly by developing improved methods for processing and conveying the sensed information to the surgeon. However, the debate of the usefulness of force feedback in robot-assisted surgery is still open and is made more complex by the many scientific and technical difficulties due to the intrinsic presence of (possibly variable) communication time delay in the robotic system [63.147].

Although the most obvious way to *display* haptic information in a telesurgical system is directly through the master hand controllers, this method has several limitations, including friction and limited bandwidth in the hand controllers. Although these issues may be addressed through specialized design (which may raise costs and require other compromises) and improved control, there has been considerable interest in *sensory substitution* schemes [63.149–151] in which force or other sensor information is displayed visually, aurally, or by other means. Figure 63.8c shows one example of sensory substitution for warning when a da Vinci robot is about to break a suture [63.63].

Starting in the 1990s, several groups [63.151–153] have *sensorized* surgical instruments for microsurgery and MIS by equipping them with force sensors. Generally, these efforts relied on sensory substitution to display force data, either for freehand or telesurgical application. For example, *Poulose et al.* [63.152] demonstrated that a force sensing instrument used together with an IBM/JHU LARS robot [63.25] could significantly reduce both average retraction force and variability of retraction force during Nissen fundoplication. The first surgical robot with force feedback used in in vivo experiments was the JPL-NASA RAMS system, which was tested on animal models for vascular anastomosis [63.154] and carotid arteriotomies [63.155]. *Rosen et al.* [63.153] developed a force-controlled teleoperated endoscopic grasper equipped with position

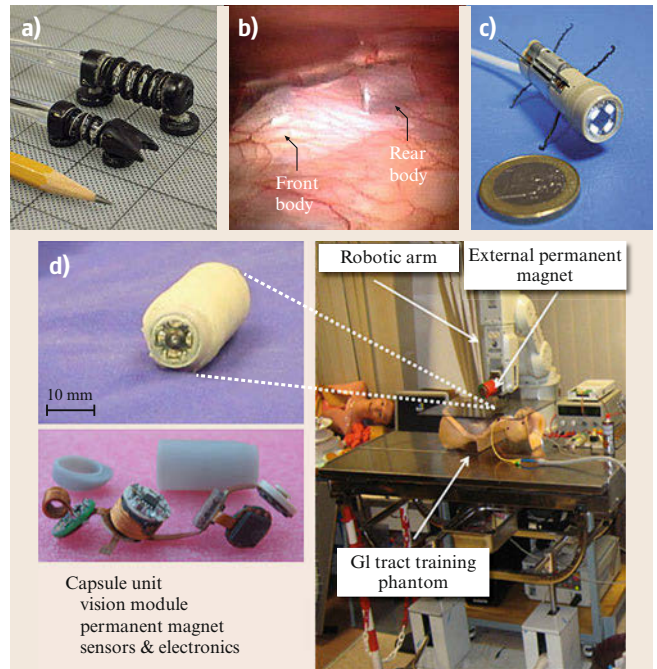

Fig. 63.11a–d Mobility inside the body. **(a,b)** *HeartLander* device for crawling across the surface of the heart (after [63.31]). **(c)** Legged capsule for gastrointestinal diagnosis and therapy (after [63.28, 148]), **(d)** magnetic capsule for exploration of the GI tract, showing *left* capsule and components and *right* magnetic dragging platform based on a permanent magnet driven by a robotic manipulator (after [63.143])

sensors and actuated by direct-current (DC) motors whose output torque is sensed and fed back through motors integrated in a grasping handle. A similar approach was used by *Menciassi et al.* [63.156] for a microsurgery gripper equipped with semiconductor strain gauges and a PHANTOM (SensAble Technologies, Inc.) haptic interface. More recent work at Johns Hopkins has focused on incorporation of optical fiber force [63.157–160] and OCT [63.161–163] sensors into microsurgical tools. Both video and auditory sensory substitution [63.164], as well as direct feedback to robotic devices have been used to help surgeons control tool-tissue interaction forces and distance.

Several researchers [63.165] have focused on specialized *fingers* and display devices for palpation tasks requiring delicate tactile feedback (e.g., for detecting hidden blood vessels or cancerous tissues beneath normal tissues). There has also been work to integrate non-haptic sensors into surgical instruments, for example, *Fischer et al.* have developed instruments measuring both force and tissue oxygenation levels [63.166]. This information can be used for such purposes as assessing tissue viability, distinguishing between different tissue

types, and controlling retraction so as not to cause ischemic tissue damage.

Finally, it is important to note that sensorized surgical tools have important application beyond their direct use in surgical procedures, for example, one use is in biomechanical studies to measure organ and tissue mechanical properties to improve surgical simulators.

63.3.8 Surgical Simulators and Telerobotic Systems for Training

Medical education is undergoing significant changes. The traditional paradigm for surgical technical training is often summarized as *see one, do one, teach one*. This method can be effective in open surgery, where the surgical trainee directly observes the expert surgeon hands, sees the instrument motion, and follows the organ manipulation. However, in endoscopic surgery it is difficult to observe the surgeon's hand movements (outside the body) and the surgical tool actions (inside the body and only visible on a video monitor). In addition, endoscopic surgery requires different skills than open surgery, such as spatial orientation, interpretation of 2-D images in 3-D, and manipulating instruments through entry portals. These considerations led to introduction of surgical simulation systems of varying degrees of complexity and realism for endoscopic and other minimally invasive procedures. Nowadays, training simulators have achieved widespread acceptance in the field of anaesthesia, intensive care, flexible endoscopy, surgery, interventional radiology, and other fields. The use of simulators for training is so common that working groups have been set up in order to evaluate these training systems based on shared guidelines [63.167] and many teaching hospitals have extensive simulation training centers. Simulators are being validated on their basic parameters (face, content and construct) [63.168], whereas results on concurrent and predictive validity of simulation training are still not available.

Survey [63.169] divides training simulators into three groups, depending on the type of technology used: mechanical, hybrid, and virtual reality.

Mechanical simulators are boxes where objects or organs are placed and manipulated using surgical instruments. The manipulation is observed through a laparoscope and a screen. The simulated surgical task is observed by an experienced surgeon, who gives feedback to the trainee. Generally, there are no registration processes and the simulator must be reassembled after any training session. The *LapTrainer with SimuVision* (Simulab Inc., Seattle, USA) is a training system with a simulated laparoscope that consists of a boom-mounted digital camera in an open box trainer.

A hybrid simulator uses a box with objects or organs as a mechanical simulator, but in addition the performance of the trainee are monitored by a computer which gives guidance for the task execution and an objective feedback based on preplanned metrics. Thanks to this feedback, the assistance and judgement of an experienced surgeon are not strictly necessary, for example, the ProMIS (Haptica Inc., Boston, USA) is a typical hybrid simulator for training basic skills such as suturing and knot tying. Surgical instruments are passed through dedicated ports and the trainee receives the same haptic feedback as in real surgery during manipulation in the box. In addition, ProMIS analyzes the trainee's performance by tracking the instrument position in 3-D and by measuring the execution time, path length, and smoothness of task execution. Another recent hybrid simulator is the Perk Tutor open-source platform for ultrasound-guided percutaneous needle insertion training [63.170], which has been successfully applied in teaching of ultrasound-guided facet joint injections [63.171]. Specific to robotic surgery is the RoSS system [63.172], which simulates the operator console of the da Vinci robotic system. Intuitive Surgical currently markets the dv-Trainer [63.173] simulator for the da Vinci system, comprising the surgeon console from a da Vinci Si system and a computer back end to simulate the patient-side manipulators, and its efficacy is being evaluated [63.174].

Finally, *virtual-reality* training systems combine visualization and haptic interfaces to enable surgeons to interact efficiently and naturally with real-time computational models of patient anatomy [63.175]. The development of these systems is inherently a multidisciplinary effort, including real-time computer graphics, the development of high-bandwidth haptic devices, real-time biomechanical modeling of organs, tool-tissue interactions, expertise in training assessment, and human-machine information exchange, etc. [63.176]. Research in these areas is closely related to and synergistic with comparable developments in technology and systems for performing real interventions, for example, modeling of organ motion in response to forces is necessary to improve the accuracy of needle placement procedures. Haptic feedback devices must meet similar requirements whether the forces displayed are simulated or measured directly in telesurgery, and so on. Finally, as noted earlier, *sensorized* instruments and real-time imaging are critical sources of data needed to create realistic biomechanical models. The use of the computer graphical processor (GPU) allows the simulation of organs at rates in excess of 10 kHz [63.177], which enables good haptic feedback. Similarly, new physics-based graphical libraries support the development of low cost virtual reality simu-

lators that correct render the interaction of instruments and anatomical parts, and thus can support large training classes [63.178].

The variety of interface devices and virtual reality laparoscopic simulators is quite wide and increasing numbers of systems are becoming commercially available. The Phantom interface is used in conjunction with virtual simulators to provide users with realistic haptic feedback (SensAble Technologies Inc., Woburn, MA, USA). The Xitact LS500 laparoscopy simulator (Xitact S.A., Lausanne, Switzerland) is a modular virtual-reality simulation platform with software for training and assessing performance in laparoscopic tasks. It is an open system including all or some of these subsystems: laparoscopic tools, mechanical abdomen, a personal computer (PC) providing the virtual-reality scenario, a haptic interface, a force feedback system and a tracking system for the tools. Several other systems for virtual reality simulation exist that exploit the hardware from Xitact or Immersion Medical, Inc. (Gaithersburg, MD, USA) and that are dedicated to specific surgical tasks: Lapmentor [63.179], the Surgical Education platform [63.180], LapSim [63.181], Procedicus MIST [63.182], EndoTower [63.183], the Reachin laparoscopic trainer [63.184], Simendo [63.185], and the Vest system [63.186]. Specifically for training eye surgeons, the surgical simulator EYESi [63.187] uses advanced computer technology and virtual reality to simulate the feel of real eye surgery, making it possible for surgeons at all levels to acquire new skills and perfect their techniques in preparation for surgery on the human eye. Training for dexterity skills in robotic surgery is supported by the new virtual simulator *XRON* developed at the University of Verona, which interfaces physics-based simulation with several commercial joysticks and provides evaluation metrics of interactive tasks [63.188].

Making a comparison between these different categories of simulators is not trivial. Basically, box trainers and hybrid simulators require some experienced technicians for the set up and some organizational logistics due to legal and ethical factors related to the storage of freshly explanted organs. The most evident advantage of these simulators is that the tactile response from the manipulated objects is the same as in real surgery and complicated models of organs and tissue-tool interaction are not required. On the other hand, completely virtual-reality trainers are potentially very flexible, can take advantage of powerful graphical engines, but they are limited by the availability of realistic calibration data for the anatomical and biomechanical models. Although demonstrations exist of the ability of simulators to record, objectively score, and hone the psychomotor skills of novice surgeons [63.189], the debate about their value is still open because no multicentre trials has yet been conducted to determine their efficacy. Furthermore, it has been shown that simulation training must be included in structured curricula in robotic surgery, where trainees are also introduced to basic concepts of robotics and, in particular, to the so called *non technical* skills, e.g., organization, leadership and communication, which significantly affect the surgical outcome [63.190].

63.3.9 Other Applications and Research Areas

The research areas described above illustrate major themes within medical robotics, but they are by no means exhaustive. Many important application areas such as otolaryngology [63.191–194] and radiation therapy have necessarily been excluded for space reasons. For a fuller exploration, readers should consult the further reading suggestions in Sect. 63.4.

63.4 Conclusion and Future Directions

Medical robotics (and the larger field of *computer-integrated interventional medicine*) has great potential to revolutionize clinical practice by:

- Exploiting technology to transcend human limitations in treating patients
- Improving the safety, consistency, and overall quality of interventions
- Improving the efficiency and cost-effectiveness of robot-assisted patient care
- Improving training through the use of validated simulators, quantitative data capture and skill as-

essment methods, and the capture and playback of clinical cases

- Promoting more effective use of information at all levels, both in treating individual patients and in improving treatment processes.

From being the stuff of late-night comedy and science fiction 20 years ago, the field has reached a critical threshold, with clinically useful systems and commercial successes. The scope and number of research programs has grown exponentially in the past 8 years, and this chapter is by no means a comprehensive survey

of the field. In fact, such a survey would be practically impossible in less than 100 pages. Many important emerging systems and applications are necessarily left out. Interested readers are urged to refer to the further reading section for more complete treatments. In particular, the survey articles and books in listed at the end of this section collectively contain somewhat fuller bibliographies than space permits here.

In the future, we can expect to see continued research in all aspects of technology and system development, with increasing emphasis on clinical applications. As this work proceeds, it is important that researchers remember several basic principles. The first, and arguably most important, principle is that medical robotics is fundamentally a *team* activity, involving academic researchers, clinicians, and industry. Each of

these groups has unique expertise, and success comes from effective, highly interactive partnerships drawing upon this expertise. Building these teams takes a long-term commitment, and the successes in recent years are largely the pay-off from investments in creating these teams. Second, it is important to work on problems with well-defined clinical and technical goals, in which the criteria for measuring success are ultimately related to real advantages in treating patients. In working toward these goals, it is important to have measurable and meaningful milestones and to emphasize rapid iteration with clinician involvement at all stages. Finally, it is essential that all team members recognize the level of commitment that is required to achieve success and that they enjoy what they are doing.

64. Rehabilitation and Health Care Robotics

H.F. Machiel Van der Loos, David J. Reinkensmeyer, Eugenio Guglielmelli

The field of rehabilitation robotics considers robotic systems that 1) provide therapy for persons seeking to recover their physical, social, communication, or cognitive function, and/or that 2) assist persons who have a chronic disability to accomplish activities of daily living. This chapter will discuss these two main domains and provide descriptions of the major achievements of the field over its short history and chart out the challenges to come. Specifically, after providing background information on demographics (Sect. 64.1.2) and history (Sect. 64.1.3) of the field, Sect. 64.2 describes physical therapy and exercise training robots, and Sect. 64.3 describes robotic aids for people with disabilities. Section 64.4 then presents recent advances in smart prostheses and orthoses that are related to rehabilitation robotics. Finally, Sect. 64.5 provides an overview of recent work in diagnosis and monitoring for rehabilitation as well as other health-care issues. The reader is referred to Chap. 73 for cognitive rehabilitation robotics and to Chap. 65 for robotic smart home technologies, which are often considered assistive technologies for persons with disabilities. At the conclusion of the present chapter, the reader will be familiar with the history of rehabilitation robotics and its primary accomplishments, and will understand the challenges the field may face in the future as it seeks to improve health care and the well being of persons with disabilities.

64.1 Overview	1686
64.1.1 Taxonomy of Rehabilitation Robotics	1686
64.1.2 World Demographics	1687
64.1.3 Short History of Rehabilitation Robotics	1688

64.2 Rehabilitation Therapy and Training Robots	1692
64.2.1 Grand Challenges and Roadblocks	1692
64.2.2 Movement Therapy After Neurologic Injury	1694
64.2.3 Robotic Therapy for the Upper Extremity	1695
64.2.4 Robotic Therapy for Walking	1699
64.3 Aids for People with Disabilities	1703
64.3.1 Grand Challenges and Enabling Technologies	1703
64.3.2 Types and Examples of Assistive Rehabilitation Robots	1705

64.1 Overview

In this chapter, we discuss an application of robotics that will likely touch many of us in an acutely personal way at some point in our lives. When, through injury or disease, we become unable to interact physically with our immediate environment as we desire to achieve our personal goals, or when one of our family members, friends, or neighbors is in this situation, technology-based solutions will likely be a major component in the treatment interventions that therapists prescribe to assist us in re-learning how to complete our activities of daily living (ADL), or to assist us in actually doing them if we are unable to recover lost function. While human therapists and attendants can indeed shoulder the types of assistance required, the projected short-term demographics of many countries, including China, Japan, and the Scandinavian countries, show a growing shortage of working-age adults. Age-related disabilities will soon substantially impact the service sector job market, put many older and disabled people at risk, and increase the need for institutionalization when there is no viable home-based solution. National programs to develop personal robots, robotic therapy, smart prostheses, smart beds, smart homes, and tele-rehabilitation services have accelerated in the past 20 years and will need to continue apace with the ever increasing ability of health care to allow people to live longer through the repression of disease and improvement in surgical and medication interventions. Rehabilitation robotics, although only a 50 year old discipline [64.1–3], is projected to have a fast-growing future in the coming decades. Within the past 10 years, the field has seen significant strides in the commercialization of rehabilitation robotics due to an increasing acceptance of the validity of this approach by clinical care providers, as well as the cost reductions in sensors and actuators. We have also witnessed the expansion of applications from the social robotics research domain into rehabilitation, increasing the range of persons whose impairments can be targeted by robotic technologies in the years to come.

64.1.1 Taxonomy of Rehabilitation Robotics

The field of rehabilitation robotics is generally divided between the categories of *therapy* and *assistance* robots, although some devices can serve both purposes. In addition, rehabilitation robotics includes aspects of artificial limb (prosthetics) development, functional neural stimulation (FNS) and technology for diagnosis and monitoring of people during activities of daily living.

Therapy robots generally have at least two main users simultaneously, the person with a disability who is receiving the therapy and the therapist who sets up and monitors the interaction with the robot. As this type of therapy is moving into the home, a third user group has also become prominent: the disabled person's caregivers and family.

The Types of therapies that have benefited from robotic assistance are upper- and lower-extremity movement therapy, communication-enabling for children with autism and exploration-enabling (education) for children with cerebral palsy (CP) or other developmental disabilities (Chap. 73). A robot may be a good alternative to a physical or occupational therapist for the actual hands-on intervention for several reasons:

1. Once properly set up by a therapist – an essential role – an automated exercise machine can consistently apply therapy over long periods of time without tiring.
2. The robot's sensors can measure the work performed by the patient and quantify, to an extent not detectable by standard clinical scales, any recovery of function that may have occurred, which may be highly motivating for a person to continue in the therapy.
3. The robot may be able to engage the patient in types of therapy exercises that a therapist cannot do, such as computer game-based therapy or magnifying movement errors to provoke adaptation [64.4, 5].

One way to classify robotic solutions for application to rehabilitation therapy is by how they contact the patient [64.6].

Operational Therapy Robots (or End-Effector-Based Therapy Robots)

For these machines, the trajectories of the robot end-effector and that of the human end-effector, e.g., the hand or the foot, are physically coupled in operational space. In joint space, the trajectories of the robot joints and of the human joints can significantly differ. Main advantages of operational therapy robots are that: (a) they can be designed by using off-the-shelf components or robots; (b) they can be easily programmed in Cartesian space by nonexpert users. Main limitations are that: (a) they are not able to assist each single human joint independently; (b) patients using these robots are supposed to feature a minimum level of residual motor synergies in order to coordinate their own multijoint movement, producing the configurations of the affected limb required by the therapy exercise.

Wearable Therapy Robots (or Exoskeleton-Based Therapy Robots)

For these machines, a larger portion of the human body (typically the whole affected limb) is in continuous physical contact with the robot. In most cases, a biomimetic exoskeleton kinematic structure is selected. In this case, not only are the trajectories of the robot and human end-effectors the same in operational space, but the trajectories of the robot joints approximate those of the human joints in joint space. The main advantage of wearable therapy robots is the possibility of sensing the configuration and assisting each human joint independently. The main drawbacks of these systems are additional design considerations needed to avoid misalignments between robot and human joints, and to minimize the invasiveness for the patient in terms of weight, dimensions, and overall wearability (Sect. 64.2.4).

Non-Contact Therapy Robots (or Socially Assistive Robotics)

Robotic devices are also being developed for rehabilitation therapy that do not physically contact the patient, but instead monitor and coach the patient during therapy [64.7]. A key concept of this approach is that humans are wired to respond to embodied agents in ways that are important for motivation in rehabilitation therapy (see Chap. 73 for a detailed discussion of socially assistive robotics). One of the earliest robotic therapy devices, developed by Erlandson, can be classified as a socially assistive robot, as it provided reaching targets for patients rather than physically assisting movement [64.8] (see later). The main advantage of noncontact therapy robots is that of being intrinsically safe, since they are not supposed to physically interact with the patient, although this could limit significantly the scope of their clinical application.

From a design perspective, it is important to understand that therapy robots are tools typically intended for temporary use (i. e., the duration of the therapy at home or at the clinic), and are designed to maximize the objective clinical effectiveness of the therapy as well as the outcome and the efficiency of the entire clinical process.

Assistive robots, instead, are solutions for promoting independent living of disabled and elderly citizens. They need to be designed to be usable in a lifelong perspective in real-life scenarios, and thus, designers need to take into account (at a much more serious level than in the case of therapy robots) the end-user subjective preferences, and human factors, in general, in order to maximize their overall, long-term acceptability [64.6]. Whereas limited usability, some level of discomfort, or bad aesthetics might be tolerated by the patients expe-

riencing the application of a therapeutic tool used in a gym or at home, these same factors are unacceptable for disabled or elderly persons who are supposed to depend upon an assistive robot for activities of daily living in a variety of social contexts for the rest of their lives.

Assistive robots can be grouped on the basis of their focus on manipulation, mobility, or cognition. Manipulation aids can further be classified into fixed-platform and portable-platform and mobile-autonomous types. Fixed-platform robots perform functions in the kitchen, on the desktop, or by the bed. Portable types are manipulator arms attached to an electric wheelchair to hold and move objects and to interact with other devices and equipment, as in opening a door. Mobile-autonomous robots can be controlled by voice or other means to do manipulation and other errands in the home or workplace. Mobility aids are divided into electric wheelchairs with navigation systems and mobile robots that act as smart, motorized walkers, allowing people with mobility impairment to lean on them for fall-prevention and stability. The third main type, cognitive aids, assists people who have dementia, autism, or other disorders that affect communication and physical well-being.

The fields of prosthetics, orthotics, and functional electrical stimulation (FES) are closely allied with rehabilitation robotics. Prostheses are artificial hands, arms, legs and feet that are worn by the user to replace amputated limbs. Prostheses are increasingly incorporating robotic features [64.9, 10]. Robotic orthoses are actuated braces that can assist a person in walking or moving the arms or hands. FES systems seek to reanimate limb movements of people who are weak or paralyzed by electrically stimulating nerve and muscle. FES control systems are analogous to robotic control systems, except that the actuators being controlled are human muscles. Another related field is technology for monitoring and diagnosing health care issues as a person performs activities of daily living.

This chapter is organized according to this taxonomy. After providing background information on demographics (Sect. 64.1.2) and history (Sect. 64.1.3) of the field, Sect. 64.2 describes rehabilitation therapy and training robots, and Sect. 64.3 describes robotic aids for people with disabilities. Section 64.4 then reviews recent advances in smart prostheses and orthoses that are related to rehabilitation robotics. Finally, Sect. 64.5 provides an overview of recent work in diagnosis and monitoring for rehabilitation as well as other health-care issues.

64.1.2 World Demographics

Different areas of rehabilitation robotics focus on different user populations, but a linking characteristic

of these populations is that they have a disability. Disability is defined in the US with the Disabilities Act as *A physical or mental impairment that substantially limits one or more of the major life activities*. Worldwide disability, based on survey results from the WHO ranges from about 10 to 40% of the population, depending on gender, age, wealth, and residence, with an overall prevalence of about 16% (Table 64.1). Prevalence is the proportion of a population who have (or had) a specific characteristic in a given time period. In medicine, typically this characteristic is an illness or impairment. Prevalence is usually expressed as a percentage (e.g., 5%), or as the number of cases per 10 000 or 100 000 people, depending on how common the illness or risk factor is in the population. Across all other parameters, there is approximately a 4 : 1 disparity in disability rates in the elderly population (>60 years) over working-class adults. In addition, lower birth rates and life-extending health care are the dominant factors contributing to the aging of the population and concomitant rise in disability overall. Other factors, such as China’s population control policies of the 1970s, have created a lack of working-age adults to support the world economy. These and other factors make it clear that rehabilitation robotics developers will be faced with users who, as a demographic group, have generally lower levels of sensory and motor capability, and may have impaired cognition as well. The urgency of making advances in this field is increasing in line with the demographics.

64.1.3 Short History of Rehabilitation Robotics

The history of rehabilitation robotics is almost as old as that of robotics itself, although emanating from very different sources. Several book chapters and papers have been written on the history of rehabilitation

robotics in more detail than this section [64.1, 19, 20], and numerous papers in the proceedings of the IEEE International Conference on Rehabilitation Robotics also provide more grounding for historical perspective. The chronology below pays particular attention to early work and to projects with notable clinical and/or commercial impact.

Early robotics, starting in the late 1950s, focused on large manipulators to replace workers in factories for dirty, dangerous, and undesirable tasks. The earliest rehabilitation robots came from the field of prosthetics and orthotics (P&O). Both the Case Western University Arm (1960s) and the Rancho Los Amigos *Golden Arm* (early 1970s) (reviewed in [64.19]) were adaptations of replacement mechanical arms meant as powered orthoses [64.1]. The user drove the *Golden Arm* with a set of tongue-operated switches, joint-by-joint, an arduous means of endpoint control. In the mid-1970s, the Department of Veterans Affairs began funding a group at the Applied Physics Lab under the guidance of *Seamone* and *Schmeisser* to computerize an orthosis mounted on a workstation to perform activities of daily living (ADL) tasks such as feeding a person and turning pages [64.21]. For the first time, a rehabilitation robot had a command-type interface, not just a joint-by-joint motion controller.

The 1970s also saw the French *Spartacus* system being developed, guided by the vision of *Vertut*, for use by people with high-level spinal cord injury (SCI) as well as children with CP [64.22]. This system did not emerge from the P&O field but was developed by the French Atomic Energy Commission (CEA), which used large tele-manipulators for nuclear fuel rod handling. One of these was adapted so that people with movement impairment could control it using a joystick for pick-and-place tasks. A decade later, one of the researchers on the *Spartacus* project, *Kwee*, began the Dutch MANUS Project [64.23] a dedicated effort to develop the first wheelchair-mounted manipulator de-

Table 64.1 Prevalence of disability and aging in selected countries (after [64.18])

Country	Number people with disabilities	Percentage of population with disabilities	Number of elderly people	Percentage of population that is elderly
France	5 146 000	8.3	12 151 000	19.6
USA	52 591 000	20.0	35 000 000	12.4
Great Britain	4 453 000	7.3	12 200 000	29.5
Netherlands	1 432 000	9.5	2 118 808	13.4
Spain	3 528 220	8.9	6 936 000	17.6
Japan	5 136 000	4.3	44 982 000	35.7
Korea	3 195 000	7.1	16 300 000	36.0
Italy	2 609 000	4.8 [64.11]	12 302 000	20.3 [64.12]
Germany	7 101 682	8.7	16 844 300	21.0 [64.13]
China	84 600 000	6.5 [64.14]	122 880 000	9.1 [64.15]
India	21 000 000	1.8 [64.16]	67 117 826	5.6 [64.17]

signed expressly as a rehabilitation robot, not adapted from a design from another field.

In between, several other major programs were begun. In 1978, at Stanford University, and then with decades-long funding from the US Department of Veterans Affairs, Leifer started the Vocational Assistant Robot program, culminating in several clinically tested versions of the Desktop robot, DeVAR [64.3, 24, 25], the mobile version, MoVAR [64.26], and finally a Professional version, ProVAR, developed by Van der Loos et al., which had the advanced ability for the user to program tasks in an easy-to-use browser-type environment [64.27]. Although DeVAR briefly made it onto the market in the early 1990s, multisite user testing revealed this industrial-arm-based approach to assistive robotics was still too costly for the low level of functionality achieved, even with ProVAR's advanced interface.

In the mid-1980s, from observations on the unsuitability of existing industrial, educational and orthosis-derived manipulators for rehabilitation applications, Tim Jones at Universal Machine Intelligence (later Oxford Intelligent Machines: OxIM) in the UK began an intensive effort to provide the rehabilitation robotics community with its first workhorse system especially designed from the ground up for human service tasks. Over 10 years, a series of systems, starting with the RTX model, were used in numerous research labs and clinics around the world. The most extensive effort to use the OxIM arm was in France, and a suite of research projects, funded by the French government and the European Research Commission, starting as RAID, then as MASTER [64.28], developed and clinically tested workstation-based assistive systems based on the RTX and subsequent OxIM arms. When OxIM ceased building its arms, the French company Afma Robotics [64.29] took over efforts to commercialize the MASTER system, although it has also stopped production.

The UK witnessed the first commercially available feeding robot, Handy-I, an inexpensive and well-received device first designed by Topping and then commercialized by Rehabilitation Robotics, Ltd. in the 1990s [64.30]. Primarily for people with CP to achieve a measure of independence in feeding themselves, task environments later also included face washing and applying cosmetics, areas of high demand identified by its users.

The history of mobile manipulator applications began in the 1980s with adaptations of educational and industrial robots, and achieved a boost with the funding of the US National Institute on Disability and Rehabilitation Research (NIDRR) for a Rehabilitation Engineering Research Center on Rehabilitation Robotics

(RERC) at the AI duPont Hospital in Delaware from 1993 to 1997. With its ability to fund dozens of research projects in parallel, it also formed a partnership with a local company, Applied Resources, Corp. (ARC), which developed and marketed several rehabilitation technology products. One of the RERC researchers, Mahoney, moved to ARC and was instrumental in extending the company's repertoire to the RAPTOR wheelchair-mounted arm [64.31].

In Europe, the most significant mobile manipulator project was the MANUS Project [64.23] mentioned earlier. With much of the work done under the direction of Kwee at the iRV (Rehabilitation R&D Center) in the Netherlands, the project culminated in a robot specifically designed for wheelchair mounting, with user control through a joystick and feedback by a small display on the arm itself. This project led to numerous follow-on research projects, and, most significantly, to the commercialization of the system by Exact Dynamics, BV, in the Netherlands. The company's current product, called the iARM, is provided on physician prescription by the Dutch Government to qualified people with a disability, such as CP or tetraplegia from an SCI.

Realizing a potential growth in this market niche, the Canadian company, Kinova Robotics, in 2009 began commercializing a competing product, called the Jaco Arm [64.32], with a different design approach. Using carbon fiber segments and lightweight actuator and control components, the payload specifications and control options are approximately the same as for the iARM, but achieved at a lower arm weight.

Autonomous navigation systems on electric wheelchairs began in the 1980s also, benefiting initially from the development by Polaroid Corp. of range finders for its cameras using ultrasonic sensors. They were inexpensive, and small enough, at 30 mm in diameter, that dozens of them could be placed around the periphery of a wheelchair to aid medium-range navigation (≈ 10 –500 cm). In the 1990s and early 2000s, with the advent of vision-based servoing and laser-range scanners, algorithms for faster, smarter, less-error prone navigation and obstacle avoidance dominated research advances in this sector. In Korea, for example, Bien et al., at the KAIST Human Welfare Robotics Center began developing the KARES line of wheelchair-based navigation systems in the late 1990s [64.33] and the NavChair project at the University of Michigan was the start of a development line that led to the commercialized Hephaestus system at the University of Pittsburgh [64.34, 35].

Therapy robots had a later start than assistive robots. Research on upper extremity therapy robots started in the mid-1980s with early exercise devices, such as the BioDex [64.36] a first step in programmable,

force-controlled, albeit single-axis devices. The first multi-axis concept was published by *Khalili and Zomlefer* [64.37], and the first tested system by *Erlandson et al.* at Wayne State University emerged in the mid-1980s as well [64.8]. The RTX manipulator had a touch-sensitive pad as an end-effector, presenting targets at different locations for patients with upper extremity weakness (e.g., following a stroke) to hit after the screen gave a visual signal. Software logged response times, thereby providing a score that was tallied and compared to previous sessions. Later robots used advanced force-based control, which required significantly more computer power. The early-1990s saw the start of the MIT-MANUS Project with Hogan and Krebs, simple robotic devices designed for bimanual therapy after stroke designed by *Lum et al.* at U.C. Berkeley [64.38, 39], followed a few years later by the Palo Alto VA MIME (mirror image motion enabler) Project [64.40] and its derivative, Driver's SEAT [64.41], with Bugar, Van der Loos and Lum, as well as the Rehabilitation Institute of Chicago ARM Guide Project with *Reinkensmeyer et al.* [64.42]. Each had a different philosophy on upper extremity stroke therapy and each was able to demonstrate clinical effectiveness in a different way. Several of these programs, now two decades later, have made significant technical advances, and all the investigators are still active in the field. Current work is described in subsequent sections of this chapter.

Research on lower extremity therapy robots began with the work of Scherb in 1919 who proposed an approach called *mechanotherapy* [64.43]. He also developed a prototype, depicted in Fig. 64.1, of a cable-driven machine for assisting the motion of the lower limbs for bedridden patients. In 1976, the use of a master/slave exoskeleton system for lower limb therapy was introduced by the French physicians *Bel and Rabischong* [64.44], who developed

Fig. 64.1 The meridian. A universal machine for applying passive motion to any joint (after [64.43])

a pneumatically actuated wearable robot to be used for assisted therapy of paraplegic patients (Fig. 64.2). The robot movements were remotely controlled by a therapist who wore a master device capable of sensing and recording the configuration of her/his lower limbs.

About 20 years later, the Lokomat project for the development of a stand-alone, programmable wearable robot for lower extremity was launched and originated the establishment of the Hocoma company by Colombo and Hostettler. The first prototype of the Lokomat system [64.45] was developed in close cooperation with the Balgrist University Hospital in Zurich and initially applied to patients who had had spinal cord injuries (Fig. 64.3b). During the same time, *Hesse and Uhlenbroch* developed the Gait Trainer [64.46], (Fig. 64.3a), which allowed training without the use of a treadmill by controlling the center of mass (COM) in both in the vertical and horizontal directions.

In the last decade the growth in rehabilitation robotics has been characterized by the development of new devices (as explained above) as well as by new investigation methods aimed at understanding brain changes induced by rehabilitation. A recent clinical study [64.50] confirms that high-intensity, repetitive, and task-oriented training yields a faster learning and recovery time. Robots are also a key-enabling technology for labor-intensive and patient-tailored training as well as for accurately imposing spatial and temporal constraints within interactive scenarios so as to augment patient involvement [64.51]. A recent international online survey, distributed through professional organizations to therapists, has set out a set of important robotic rehabilitation device requirements [64.52], such as variety of arm movements, biofeedback to patients, adjustable resistance, and need for virtual activities. Robots offer the advantage of providing ob-

(USA), **(d)** LokoStation with Lokohelp (Darkov Spa, Czech Republic; after [64.48]), **(e)** G-EO Evolution (Panos Th. Skoutas S.A., Greece; after [64.49])

jective measures of user performance, thus enabling the development of quantitative kinematic and dynamic metrics [64.53–56]. The analysis of brain reorganization and associated clinical outcomes induced by robot-aided therapy in chronic stroke patients have shown that motor performance improvement is correlated with changes in inter-hemispheric connectivity between primary somatosensory areas: for those patients the connectivity returns to nearly *physiological levels* [64.57].

Protocols based on monitoring patient performance, strength, endurance, and emotional state are being investigated. Anticipating patient movement intentions and modeling internal states lead to adaptive patient–

robot interaction control. This approach paves the way to a new generation of robotic therapy devices using *bio-cooperative* controllers, where *psychophysiological* and biomechanical information is used as feedback for updating robot control [64.58–60]. First examples of biocooperative controllers can be found in the robotic platforms developed within the European projects ECHORD/MAAT [64.56] (multimodal interfaces to improve therapeutic outcomes in robot-assisted rehabilitation) (Fig. 64.4) and MIMICS (multimodal immersive motion rehabilitation with interactive cognitive systems). Other bio-cooperative controllers have been developed by *Riener* and *Munih* [64.58], who developed new control strategies applied to lower limb

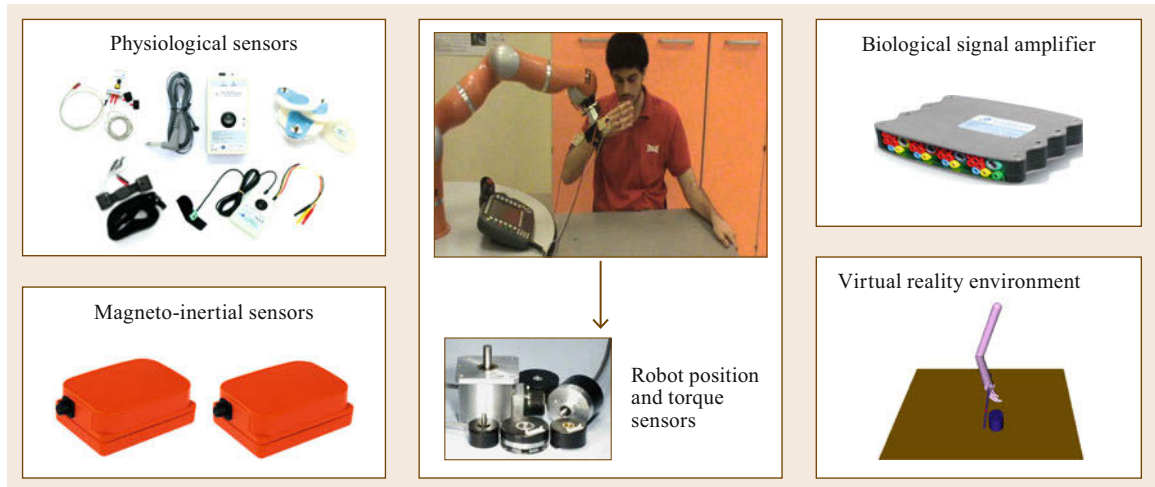

Fig. 64.4 Set up of the MAAT platform (after [64.61])

Fig. 64.5 PARO, an advanced interactive robot developed by AIST (after [64.62])

rehabilitation protocols that promote active participation of patients during training.

Cognitive robotics had started in the early 1980s to aid children with communication disorders and physical impairment to achieve a measure of control of their physical space. Using mostly educational manipulators, several demonstration systems were developed.

In the early 2000s, Latham of Anthrotronix, Inc. commercialized small robot systems to enable children with physical disabilities to play games with simple interfaces. A bit later, small mobile robots were used in clinics by *Dautenhahn* and *Werry* [64.63] with children who had autism, since robots have such simple interfaces that they appear not to be that challenging as communication with other humans. The early 2000s also saw the advent of pet robots, such as the Paro seal robot developed by *Shibata* et al. [64.64] (Fig. 64.5), as companions for both children and the elderly who are confined to clinics and have limited real companionship. This topic is further elaborated in Chap. 73.

The applications for robotics continues to increase in number as advances in materials, control software, higher robustness, and the diminishing size of sensors and actuators allow designers to attempt new ways of using mechatronics technology to further the well-being of people with disabilities.

64.2 Rehabilitation Therapy and Training Robots

The human neuromuscular system exhibits use-dependent plasticity, which is to say that use alters the properties of muscles and neurons, including the pattern of their connectivity, and thus their function [64.65–67]. For a detailed description of patient populations expected to benefit from robot-assisted therapy and the most common impairments to be treated, which include incoordination, abnormal synergies, spasticity and weakness, please see [64.50, 68–70].

64.2.1 Grand Challenges and Roadblocks

The process of neurorehabilitation seeks to exploit use-dependent plasticity in order to help people to relearn how to move following neuromuscular injuries or diseases. Neurorehabilitation is typically provided by skilled therapists, including physical, occupational, and speech therapists. This process is time-consuming, involving daily, intensive movement practice over many

weeks. It is also labor-intensive, requiring hands-on assistance from therapists. For some tasks, such as teaching a person with poor balance and weak legs to walk, this hands-on assistance requires that the therapists have substantial strength and agility to provide safe and effective interventions.

Because neurorehabilitation is time and labor intensive, in recent years healthcare players have put limits on the amount of therapy that they will reimburse in an effort to contain spiraling healthcare costs. Ironically, at the same time, there has been increasing scientific evidence that more therapy can in many cases increase movement recovery via use-dependent plasticity [64.71]. As robotics and rehabilitation researchers began to recognize beginning in the late 1980s, neurorehabilitation is a logical target for automation because of its labor-intensive, mechanical nature, and because the amount of recovery is linked with the amount of repetition. Robots could deliver at least the repetitive parts of movement therapy at lower cost than human therapists, allowing patients to receive more therapy, recover more function, remain independent longer, and reduce downstream healthcare expenses.

The grand challenge for automating movement therapy is determining how to optimize use-dependent plasticity. That is, researchers in this field must determine what the robot should do in cooperation with the patient's own movement attempts in order to maximally improve movement ability, all the while engaging the patient. Meeting this challenge involves solving two key problems: determining appropriate movement tasks (what movements should patients practice and what feedback should they receive about their performance), and determining an appropriate pattern of mechanical input to the patient during these movement tasks (in other words, at what magnitude, how often, and in which directions, should the robot apply forces to the patient's limb to provoke increased plasticity). The prescription of movement tasks and mechanical input fundamentally constrains the mechanical and control design of the robotic therapy device.

There are three main roadblocks to achieving the grand challenge. The first is a scientific roadblock: neither the optimal movement tasks nor the optimal mechanical inputs are known. The scientific basis for neurorehabilitation remains ill-defined, with competing schools of thought. The number of large, randomized, controlled trials that have rigorously compared different therapy techniques is still small, in part because these trials are expensive and difficult to control well. Therefore, the first problem that a robotics engineer will encounter when setting out to build a robotic therapy device is that there is still substantial uncertainty as to what exactly the device should do.

This uncertainty corresponds to an opportunity to use robotic therapy devices as scientific tools themselves. Robotic therapy devices have the potential to help identify what exactly provokes plasticity during movement rehabilitation, because they can provide well-controlled patterns of therapy. They can also simultaneously measure the results of that therapy. Better control over therapy delivery and improved quantitative assessment of patient improvement are two desirable features for clinical trials that have often been lacking in the past. Recent work with robotic movement training devices is leading, for example, to the characterization of computations that underlie motor adaptation, and then to strategies for enhancing adaptation based on optimization approaches [64.5, 72, 73]. Early work at UBC on the characterization of human balance in quiet standing will lead to the ability to use robotics clinically to develop new therapies to prevent falls for stroke survivors and others with balance impairment [64.74, 75].

The second roadblock is a technological one: robotic therapy devices often have as their goal to assist in therapy of many-body degrees of freedom (e.g., the arms and torso for reaching, or the pelvis and legs for walking). The devices also require a wide dynamic bandwidth such that they can, for example, impose a desired movement on a patient who is paralyzed, but also *fade-to-nothing* as the patient recovers. Further, making the devices lightweight enough to be wearable is desirable, so that the patient can participate in rehabilitation in a natural setting (for example, by walking over ground or working at a counter in a kitchen), or even throughout the course of normal activities of daily living. The development of high degree-of-freedom, wearable, high-bandwidth robotic exoskeletons is an unsolved problem in robotics, although much progress has been made toward this goal in the last 10 years, as described below. Still, no device at present comes close to matching the flexibility of a human therapist, in terms of assisting in moving different body degrees of freedom in a variety of settings (e.g., walking, reaching, grasping, neck movement), or the intelligence of a human therapist, in terms of providing different forms of mechanical input (e.g., stretching, assisting, resisting, perturbing) based on a real-time assessment of the patient's response.

The third roadblock is maintaining the motivation and engagement of the patient through the tens of thousands of repetitions required to achieve meaningful increases in function [64.50] that will carry over to performing actual ADLs. Rehabilitation can be compared to the exercise required by an athlete to compete at an elite competition level. By necessity, therapy at this intensity will have to move largely to the home setting to be economically viable, and therefore motivation

becomes the key ingredient of success. Current work focuses on developing adaptive therapy through robotics and feedback, embedding therapy in computer games, music, and sport, and applying motor-learning theories, for example, the *Challenge Point* [64.76] model of keeping people at a desirable difficulty level, to maximize effectiveness and minimize frustration over the long term [64.76]. Meeting the grand challenge of robotic therapy therefore will require substantial, inter-related advances in clinical neuroscience, robot engineering, and kinesiology.

64.2.2 Movement Therapy After Neurologic Injury

Modern, evidence-based medicine relies on objective evaluation and quantitative comparative analysis of the impact of different therapeutic approaches. Robotics technology has the potential to boost evidence-based neurorehabilitation: therapy robots provide precise and sensitive tools for assessing and modeling human behavior, well beyond the capability of a human observer. This is of paramount importance for enabling appropriate initial diagnosis, early adoption of corrective clinical strategies, and for identifying verifiable milestones as well as prognostic indicators of the recovery process.

Bosecker et al. [64.77] tried to evaluate clinical scores during upper limb therapy by means of robot-based metrics; *Zollo et al.* [64.54, 78] evaluated robotic therapy exploiting robotic outcome; thus providing quantitative measure of biomechanical and motion planning features of arm motor control following upper limb rehabilitation. A recent study carried out by *Krebs et al.* showed that robotic measurements of arm movements after upper limb, robot-aided therapy may establish biomarkers for motor recovery [64.79]. Similarly, *Domingo and Lam* [64.80] tried to apply robot-based assessment to the lower limb by using the Lokomat system and customized software.

Another important advantage of therapy robots is the possibility that a single operator can effectively supervise multiple patients, locally or even remotely, i. e., in a telerehabilitation scenario [64.81]. Therapy robots can potentially improve patients' access to rehabilitation by providing the opportunity to increase the duration and the frequency of their therapy experience, with limitations mainly depending on clinical considerations rather than on other organizational or economic constraints.

At present, much of the activity in physical therapy and training robots has been focused on retraining movement ability for individuals who have had a stroke or **SCI**, or are affected by **CP**. The main reasons

for this emphasis are that there are a relatively large number of patients with these conditions, the rehabilitation costs associated with them are high, and because these patients can sometimes experience large gains with intensive rehabilitation because of use-dependent plasticity.

A stroke refers to an obstruction or breakage of a blood vessel supplying oxygen and nutrients to the brain. Approximately 800 000 people suffer a stroke each year in the United States, and about 80% of these people experience acute movement deficits [64.82]. In Europe, 1 100 000 people suffered a stroke in 2000, and they are expected to increase up to 1 500 000 in 2025. There are over 3 000 000 survivors of stroke in the United States [64.83], with over half of these individuals experiencing persistent, disabling, movement impairments. Data are similar to those of Europe, where it has been estimated that between half and two-thirds of people survive stroke. Of these, half do not recover fully, and a quarter need assistance in daily living. While most of the survivors of stroke are elderly persons, motor impairment from a stroke affects 3000 of the 10 000 children born with **CP** each year [64.83]. While this is a small proportion of all stroke survivors, the motor function impairment will persist throughout the person's entire life, so the impact on independence is disproportionately large.

The number of people who have experienced and survived a stroke is expected to increase substantially in the United States and other industrialized countries in the next two decades, mostly because age is a risk factor for stroke and the mean age of people in industrialized countries is rapidly increasing due to the baby boom of the 1950s, but also because improved acute treatments will allow more people to survive a stroke, albeit perhaps with impairment.

The number of people who experience an **SCI** in the United States each year is relatively smaller – about 15 000, with about 200 000 people alive who have survived an **SCI** – but the consequences can be even more costly than stroke [64.82]. In Europe, there are about 11 000 new cases of **SCI** per year, and about 330 000 have survived an **SCI** [64.84]. The most common causes of **SCI** are automobile accidents and falls. These accidents crush the spinal column and contuse the spinal cord, damaging, or destroying neurons within the spinal cord. Lower limb robotic therapy has demonstrated promising results when applied to **SCI** patients with incomplete lesions [64.85] although large, systematic, and randomized controlled trials are still missing. It is important to note that **SCI** patients are typically younger than stroke patients, which may affect their familiarity with and acceptance of technical aids.

64.2.3 Robotic Therapy for the Upper Extremity

This section first describes early, clinically tested upper limb therapy robot systems (Fig. 64.6a–e), then more recent systems.

MIT-MANUS

The first robotic therapy device to undergo extensive clinical testing, and, now, to achieve some commercial success, is the MIT-MANUS, sold as the InMotion2 by Interactive Motion, Inc. [64.86]. MIT-MANUS is a planar two-joint arm that makes use of the SCARA configuration, allowing two large, mechanically grounded motors to drive a lightweight linkage. The patient sits across from the device, with the weaker hand attached to the end-effector, and the arm supported on a table with a low-friction support. By virtue of the use of the SCARA configuration, the MIT-MANUS is perhaps the simplest possible mechanical design that allows planar movements while also allowing a large range of forces

to be applied to the arm without requiring force feedback control.

MIT-MANUS assists the patient in moving the arm across the table-top as the patient plays simple video games, such as moving a cursor into a target that changes locations on a computer screen. Assistance is achieved using a position controller with an adjustable impedance. Additional modules have been developed for the device for allowing vertical motion [64.87], wrist motion [64.88], and hand grasp [64.89]. Software has been developed for providing graded resistance as well as assistance to movement [64.90], and for varying the firmness and timing of assistance based on real-time measurements of the patient's performance on the video games [64.91].

MIT-MANUS has undergone extensive clinical testing in several studies, summarized as follows. The first clinical test of the device compared the motor recovery of acute stroke patients who received an additional dose of robot therapy on top of their conventional therapy, to that of a control group, who received con-

Fig. 64.6a–e Arm-therapy robotic systems that have undergone extensive clinical testing; (a) MIT-MANUS, developed by Hogan, Krebs, and colleagues at the Massachusetts Institute of Technology (USA), (b) MIME, developed at the Department of Veterans Affairs in Palo Alto in collaboration with Stanford University (USA), (c) GENTLE/s developed in the EU, (d) ARM-Guide, developed at the Rehabilitation Institute of Chicago and the University of California, Irvine (USA), and (e) Bi-Manu-Track, developed by Reha-Stim (Germany)

ventional therapy and a brief, sham exposure to the robot [64.92]. The robot group patients received the additional robotic therapy for an hour each day, five days per week, for several weeks. The robot group recovered more arm movement ability than the control group according to clinical scales, without any increase in adverse effects such as shoulder pain. The improvements might subjectively be characterized as *small but somewhat meaningful to the patient*. The improvements were sustained at a three-year follow-up.

This first study with MIT-MANUS demonstrated that acute stroke patients who received more therapy recover better, and that this extra therapy can be delivered by a robotic device. It did not answer the question as to whether the robotic features of the robotic device were necessary. In other words, it may have been that patients would have also improved their movement ability if they had practiced additional movements with MIT-MANUS with the motor's off (thus making it equivalent to a computer mouse), simply by virtue of the increased dose of movement practice stimulating use-dependent plasticity. Thus, while this study indicated the promise of robots for rehabilitation therapy, it did not close the gap of knowledge as to how external mechanical forces provoke use-dependent plasticity.

Subsequent studies with MIT-MANUS have confirmed that robotic therapy can also benefit chronic stroke patients [64.93]. The device has been used to analyze different types of therapies, for example, to compare assisting movement versus resisting movement in chronic stroke subjects, but with inconclusive results: both types of therapies produced benefits [64.90]. The device has also been used to compare assistive robot therapy with another technological approach to rehabilitation – electrical stimulation of finger and wrist muscles [64.94]. Again, significant benefits were found for both therapies, and those benefits were specific to the movements practiced, but the benefits were not significantly different between therapies. We note that the lack of a significant difference in these studies may simply be due to the limited number of patients who participated in these studies (i.e., inadequate study power), rather than a close similarity of the effectiveness of the therapies.

As mentioned above, the MIT-MANUS device was recently tested in a multisite clinical trial funded by the Department of Veterans Affairs in the United States [64.50]. This study compared clinical outcomes in chronic stroke survivors who were randomized to three groups: usual care, robot-assisted therapy with arm, wrist, and hand modules, and one-on-one therapy with a rehabilitation therapist that was dose matched to the robotic therapy in terms of the number of move-

ments achieved per therapy session. The robot-assisted therapy group improved their movement ability more than the usual care, and about the same as the dose-matched group. This is an important finding for the field, as it demonstrated with the highest scientific rigor that robotic therapy was about as effective as an intense, therapist-delivered therapy.

A cost-benefit analysis of this study suggested that although both robotic and intense, therapist-based therapies were more expensive to deliver than usual care, it reduced long-term follow-up costs, so that the total cost of care of the patients was the same over the duration of the study [64.95]. Thus, as the cost of robotic therapy devices decreases, it should be possible to provide patients with improved outcomes while reducing the cost of therapy – another important finding.

MIME

Another early system to undergo clinical testing was the **MIME** (mirror-image movement enhancer) system, which used a Puma-560 robot arm to assist in movement of the patient's arm [64.96]. The device is attached to the hand through a customized splint and a connector that is designed to break away if interaction forces become too large. Compared to MIT-MANUS, the device allows more naturalistic motion of the arm because of its six degrees of freedom (**DOF**), but must rely on force feedback so that the patient can drive the robot arm. Four control modes were developed for **MIME**. In the passive mode, the patient relaxes and the robot moves the arm through a desired pattern. In the active assist mode, the patient initiates a reach toward a target, indicated by physical cones on a table top, which then triggers a smooth movement of the robot toward the target. In the active-constrained mode, the device acts as a sort of virtual ratchet, allowing movement toward the target, but preventing the patient from moving away from the target. Finally, in the mirror-image mode, the motion of the patient's less impaired arm is measured with a digitizing linkage, and the impaired arm is controlled to follow along in a mirror-symmetric path. The initial clinical test of **MIME** found that chronic stroke patients who received therapy with the device improved their movement ability about as much as patients who received conventional table-top exercises with an occupational therapist [64.96]. The robot group even surpassed the gains from human-delivered therapy for the outcome measures of reaching the range of motion and strength at key joints of the arm. A follow-on study attempted to elucidate which of the control modes or what combination of **MIME** exercises caused the gains, but was inconclusive [64.97]. A multisite randomized control of **MIME** again funded by the Department of Veterans Affairs compared the

effect of a high-dose (30 h) of additional therapy with **MIME**, to a lower dose (15 h), to 15 h of additional conventional therapy in 54 acute stroke patients [64.98]. Gains in the primary outcome measure, the Fugl-Meyer assessment, were not significantly different between the groups at the 6-month follow-up, although there the actual dose of robotic therapy patients received predicted their recovery.

ARM Guide

The question of the effect of robot forces on movement recovery was also left unresolved by a study with another device, the **ARM Guide**, which is a trombone-like device that can be oriented then locked in different directions, and can assist people in reaching in a straight line. Chronic stroke patients who received assistance during reaching with the robot improved their movement ability [64.99]. However, they improved about as much as a control group that simply practiced a matched number of reaches without assistance from the robot. This suggests that movement effort by the patient is a key factor for recovery, although the small sample size of this study limited the ability to resolve the size of the difference between guided and unguided therapies.

Bi-Manu-Track

Perhaps the most striking clinical results generated so far have come from one of the simplest devices built. Similar to a design proposed previously by Lum et al. [64.39], the Bi-Manu-Track uses two motors, one for each hand, to allow bimanual wrist-flexion extension [64.100]. The device can also assist in forearm pronation/supination if it is tilted downward and the handles are changed. In an extensive clinical test of the device, 22 subacute patients (i.e., 4–6 weeks after stroke) practiced 800 movements with the device for 20 minutes per day, five days per week for six weeks [64.100]. For half the movements, the device drove both arms, and for the other half, the patient's stronger arm drove the motion of the more impaired arm. A control group received a matched duration of electrical stimulation (**ES**) of their wrist extensor muscles, with the stimulation triggered by voluntary activation of their muscles when possible, as measured by electromyography (**EMG**). The number of movements performed with **EMG**-triggered **ES** was 60–80 per session. The robot-trained group improved by 15 points more on the Fugl-Meyer scale, a standard clinical scale of movement ability with a range from 0 to 66 points in upper extremity function. It assigns a score of 0 (cannot complete), 1 (completes partially), or 2 (completes normally) for 33 test movements, such as lifting the arm without flexing the elbow. For compar-

ison, reported gains in Fugl-Meyer score after therapy with the MIT-MANUS and **MIME** devices ranged from 0 to 5 points [64.101].

Other Early Devices to Undergo Clinical Testing

Other early devices to undergo clinical testing are as follows. The GENTLE/s system uses a commercial robot, the HapticMaster, to assist in patient movement as the patient plays video games. The HapticMaster allows four degrees of freedom of movement and achieves a high bandwidth of force control using force feedback. Chronic stroke patients who exercised with GENTLE/s improved their movement ability [64.102, 103]. The Rutgers **ARM** robotic device uses low-friction pneumatic cylinders to help extend or flex the fingers, and has been shown to improve hand movement ability of chronic stroke subjects [64.104]. Simple force-feedback controlled devices, including a 1-DOF wrist manipulator and a 2-DOF elbow-shoulder manipulator, were also recently shown to improve movement ability of chronic stroke subjects who exercised with the devices [64.105]. A passive exoskeleton, the T-WREX arm orthosis, provides support to the arm against gravity using elastic bands, while still allowing a large range of motion of the arm [64.106]. By incorporating a simple hand-grasp sensor, this device allows substantially weakened patients to practice simple virtual reality exercises that simulate functional tasks such as shopping and cooking. Chronic stroke patients who practiced exercising with this nonrobotic device recovered significant amounts of movement ability, comparable with the Fugl-Meyer gains seen with MIT-MANUS and **MIME**. A randomized controlled trial of T-WREX in 28 chronic stroke subjects compared therapy with the device to conventional, table-top therapy [64.107] and found that the device was slightly more effective in improving patient's motor ability at the six-month follow-up according to the primary outcome measure, the Fugl-Meyer score, and that patients strongly preferred exercising with the device. T-WREX has been commercialized as the Armeo Spring upper extremity training device by Hocoma, and was in use in over 500 clinics as of early 2014, with published reports studying its use for individuals with multiple sclerosis [64.108], **SCI** [64.109], and proximal humeral fracture [64.110]. NeReBot is a 3-DOF wire-based robot that can slowly move a stroke patient's arm in spatial paths. Acute stroke patients who received additional movement therapy beyond their conventional rehabilitation therapy with NeReBot recovered significantly more movement ability than patients who received just conventional rehabilitation therapy [64.111]. RehaRob uses an industrial robot arm to mobilize patients' arms along arbitrary trajectories following stroke [64.112].

Further Research and Developments on Robotic Therapy for the Upper Extremity

One recent trend in the field is to develop devices that can provide therapy for a larger number of degrees of freedom of the arm. For example, at the high end of cost and complexity are the ARMin [64.113], Pneu-WREX [64.114], and BONES [64.115], which are exoskeletons that accommodate nearly naturalistic movement of the arm while still achieving a wide range of force control. A system that couples a immersive virtual reality display with a haptic robot arm is described in [64.116]. A wearable exoskeleton driven by pneumatic muscles is described in [64.117]. Several other exoskeletal machines have been proposed to jointly train arm and wrist, such as the CADEN-7, an anthropometric 7-DOF powered exoskeleton system [64.118]; the SUEFEL-7, which exploits EMG signals to adjust impedance parameters [64.119]; a lightweight exoskeleton described in [64.120], and the highly redundant 9-DOFs machine introduced in [64.121].

Another area of active development in robotic therapy devices for the upper extremity is to devices that can be used at home or in rank-and-file clinics. For example, at the lower end of cost/complexity are devices that use force feedback joysticks and steering wheels with a view toward implementation in the home [64.114–125]. In 2008, a planar machine for upper limb rehabilitation designed for delivering at-home neurorehabilitation, namely CBM MOTUS, was developed and patented [64.126] (Fig. 64.7). Such a device has low inertia and highly isotropic behavior. Recently, a passive module has been developed to be installed on the CBM-MOTUS, able to further reduce robot perceived inertia when the machine is moved by the patient, while being highly rigid when the machine assists the patient's movements.

As far as wearable robotic systems for the upper limb are concerned, Hocoma engineered and com-

mercialized the ARMEO power system, and also the ArmeoSpring and ArmeoBoom machines [64.108].

A third area in robotic therapy devices for the upper extremity that has received increased attention is to develop devices for hand rehabilitation, since hand movement ability is essential for functional recovery. Examples of recent, novel robotic devices for the hand are the Haptic Knob for grasping and wrist pronation/supination [64.128]; the HandCARE, a cable-actuated rehabilitation system [64.129]; a device for repeating controlled passive movements of paralyzed fingers given in [64.130]; the exoskeletal machines HWARD [64.131], and HEXORR [64.132] to help open and close the hand; the 18-DOFs highly redundant Gifu Haptic Interface [64.133], able to produce adduction–abduction and flexion–extension finger movements. Other devices are presented in [64.134–138], and a review of robotic therapy of the hand is given in [64.139]. One robotic therapy system for the hand incorporates the idea of using visual feedback distortion to enhance motivation of patients during movement therapy [64.140]. A few commercial machines are available, such as the Reha-Digit, Amadeo, and ManovoSpring.

Based on the availability of modular hand, wrist, and shoulder–elbow therapeutic robotic devices, some recent studies tried to tackle the fundamental question of whether proximal or distal treatment differentially affect the recovery of arm/hand function. For more information of these preliminary studies, see references [64.100, 141, 142].

An important recent development in robotic therapy devices is the development of devices that can be used in conjunction with the instrumentation needed to measure neurophysiological signals, such as functional magnetic resonance imaging (fMRI)-compatible systems [64.143, 144] or, more generally, brain-imaging (BI)-compatible robotic systems that can be used in conjunction not only with fMRI but also with magne-

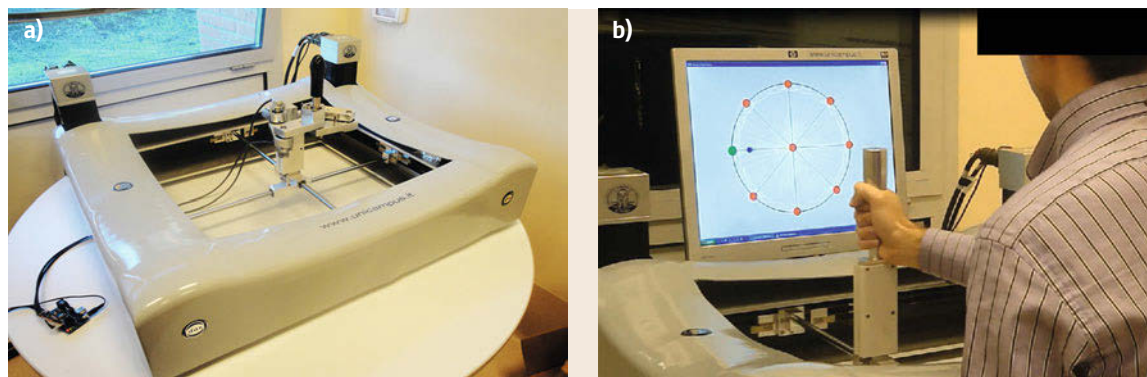

Fig. 64.7a,b CBM Motus robot for upper limb rehabilitation (after [64.127])

toencephalography (MEG), transcranial magnetic stimulation (TMS), repetitive TMS (rTMS), transcranial direct current stimulation (tDCS), near infrared spectroscopy (NIRS) and other brain imaging and stimulation equipment. Such devices are notable because they will allow a systematic scientific study of neural recovery during robotic therapy. Developing these devices requires dealing with the problems of electromagnetic compatibility and interaction.

Recently, a few fMRI-compatible devices for hand rehabilitation have been designed to acquire functional imaging while performing therapeutic exercises, such as the exoskeletal machine in [64.145]; the pneumatic actuated 2-DOF device to help wrist pronation/supination and hand open/closure in [64.146]; machines driven by electro-rheological fluids, able to provide a variable resistance to patient motion [64.147]; the planar device to help move fingers described in [64.148]. A passive fMRI-compatible manipulator morphologically similar to MIT-MANUS has been developed and tested to acquire functional imaging in [64.149]. Another study proposed the applications of a brain-computer interface (BCI) therapy approach on a cohort of stroke patients, [64.150]; a magnetoencephalography-based BCI system is used which in turn raised or lowered a screen cursor in the direction of a target. Results suggest that volitional control of neuromagnetic activity features recorded over central scalp regions can be achieved with BCI training after stroke.

Finally, the primary paradigm that has been tested so far with upper extremity robotics is to assist patients in moving, a strategy which may in some cases have the unintended affect of causing patients to *slack* [64.151]. In general, the field is still relatively undeveloped in its ability to identifying the most appropriate forms of robotic intervention given the nature of the impairment and the patient. For example, an approach opposite to physical assistance, which is using robotic force fields to amplify the kinematic errors of stroke patients during reaching, may provoke novel forms of the adaptation of those patterns [64.4, 152]. A major emphasis of the field in the next 10 years will be improving the mechanistic understanding of how robotic interaction influences brain plasticity.

64.2.4 Robotic Therapy for Walking

Scientific evidence that gait training improves the recovery of mobility after neurologic injury started to accumulate in the 1980s through studies with cats. Cats with SCI can be trained to step with their hind limbs on a treadmill with the partial support of body weight and assistance of leg movements [64.153, 154].

Following the animal studies, various laboratories developed a rehabilitation approach in which the patient steps on a treadmill with the body weight partially supported by an overhead harness and assistance from therapists [64.155–158]. Depending on the patient's impairment level, from one to three therapists are needed for BWSTT (body-weight supported treadmill training), with one therapist assisting in stabilizing and moving the pelvis, while two additional therapists sit next to the treadmill and assist the patient's legs in swing and stance. This type of training is based on the principle of generating normative, locomotor-like sensory input that promotes the functional reorganization and recovery of the injured neural circuitry [64.159]. In the 1990s, several independent studies indicated that BWSTT improves stepping in people with SCI or hemiplegia after stroke [64.155–157].

Gait training is particularly labor-intensive and strenuous for therapists, so it is an important target for automation. The efforts of roboticists have been especially focused on BWSTT rather than over-ground gait training because BWSTT is done on a stationary setup in a well-defined manner and thus can be more easily automated than over-ground gait training. Randomized, controlled clinical trials have shown that BWSTT is comparable in effectiveness to conventional physical therapy for various gait-impairing diseases [64.160–166]. These trials support the efforts toward the automation of BWSTT, as the working conditions of physical therapists will improve if the robots do much of the physical work, which, in the case of BWSTT, actually leads to occasional back injuries to therapists. Usually, only one therapist is needed in robot-assisted training, for the tasks of helping the patient into and out of the robot and monitoring the therapy. In the case of SCI patients, a small randomized, controlled trial [64.161] reported that robotic-assisted BWSTT with a first-generation robot required significantly less labor than both conventional overground training and therapist-assisted BWSTT, with no significant difference found in effectiveness.

Gait-Training Robots in Current Clinical Use

Some gait-training robot systems are commercially available and are used for therapy in several clinics worldwide, such as the gait trainer GT-I [64.46], the Lokomat [64.45] the ReoAmbulator, the Loko-Help [64.167], and the G-EO System [64.168] (Fig. 64.3a–e).

Of these robots, the GT-I (commercialized by Reha-Stim) is the one that departs most from therapist-assisted BWSTT, since it interacts with the patient's lower limbs through two footplates rather than acting on the shank as human therapists do. It also ap-

pears to depart more from natural walking because the footplate principle substantially alters the sensory cues of the foot impact with the ground or treadmill band. The GT-I footplates are driven by a singly actuated mechanism that moves the foot along a fixed gait-like trajectory with a doubled crank and rocker system [64.46]. The stride length can be adjusted between sessions by changing gears. The body weight is unloaded as needed by an overhead harness. The torso is moved sagittally in a phase-dependent manner by ropes attached to the harness and connected by another crank to the foot crank. The GT-I is currently installed in dozens of clinics, mainly in Europe. One randomized, controlled study has been reported that tested the GT-I with 30 subacute stroke patients [64.169]. The robot group improved their overground walking ability more than the control group, although differences were not significant at a 6-month follow-up. A total of 80% of the patients said they preferred training with the robot rather than the therapists because training with the robot was less demanding and more comfortable. The other 20% of patients stated that swinging of the paretic limb seemed less natural and thus less effective when training with the robot. Robot-assisted training required an average of one therapist per patient, while therapist-assisted training required two therapists per patient on average. A follow-up, randomized controlled study comparing conventional training plus robotic training with the GTI, to a time-matched amount of conventional training alone with subacute stroke patients, found that the group that received some robotic training recovery walking ability to a great extent [64.170]. More recent clinical tests with the GT I are reported in [64.171].

The Lokomat (commercialized by Hocoma) is a robotic exoskeleton worn by the patients during treadmill walking [64.45]. Four motorized joints (two per leg) move hip and knee. The actuators consist of ball screws connected to dc motors. The legs are driven in a gait-like pattern along a fixed position-controlled trajectory. The device attaches to the thighs and shanks through padded straps. A parallelogram mechanism allows the vertical translation of the patient's torso, restricting lateral translation. The patient's body weight is actively unloaded as needed through an overhead harness. The Lokomat is currently being used in over 100 clinics worldwide. In 2005, Wirz et al. [64.85] reported preliminary results of robot-assisted BWSTT with the Lokomat in 20 chronic incomplete SCI patients. The improvements in overground walking speed and endurance were statistically significant: approximately 50% gain on average in the 16 patients who were ambulatory before training. There were no significant changes in the requirement

of walking aids, orthoses, or external physical assistance. The improvements appear to be comparable to those achieved by similar SCI patients who received therapist-assisted BWSTT [64.161, 172]). For the case of stroke patients, however, therapy with the Lokomat was beneficial but about half as effective as treadmill-based or therapist-based training in improving overground gait velocity and endurance [64.173, 174].

The ReoAmbulator (commercialized by Motorika and marketed in the United States as AutoAmbulator) consists of two robotic arms that assist patients to step on a treadmill with their body weight supported as needed. The interface to the patient's legs is through straps at the thigh and ankle. The ReoAmbulator is currently being used in at least 57 HealthSouth rehabilitation centers, all of them in the United States, but little data have been published concerning its use.

The LokoHelp (commercialized by LokoHelp Group) assists users' feet motion along physiological trajectories while walking on a treadmill, also providing body weight support. Clinical trials [64.167, 171, 175] show that therapeutic outcomes are similar to manual training with reduced therapist effort.

The G-EO system (commercialized by Reha Technology) is also based on the footplate principle as for the GT I system. Studies with stroke survivors [64.176], patients with SCI [64.177] and with Parkinson's disease [64.178] have recently shown the value of this particular device.

Further Research and Developments on Robotic Therapy for Walking

Several groups worldwide are working toward improving gait-training robotic technologies. A great deal of effort has been made to incorporate and investigate the ability to assist as needed [64.72, 179–183], that is, the ability of the robot to let the patients contribute to the locomotor efforts as much as they are able. This is likely essential for maximizing locomotor plasticity [64.184]. Some effort has also been directed toward adding more active DOFs, particularly for torso manipulation [64.182, 185]. These robotic tools are needed not only for their potential clinical use in therapy, but for studying what aspects of the assistance are important for effective gait training and how best to control and implement them with robotic devices.

The team responsible for the GT-I has developed the Haptic Walker [64.179], which maintains the permanent foot/machine contact but allows the footplates to move along 3-DOF trajectories. In addition, it incorporates force feedback and compliance control, as well as haptic simulation of ground conditions (e.g., stair climbing).

An advanced version of the Lokomat integrates force sensors and automatic adaptation of gait patterns to allow for a reduction of the interaction effort between patient persons and machine [64.180]. It has been tested on unimpaired persons and SCI patients, who were able to influence the gait trajectories toward a more desired motion by means of their own motor activity [64.180, 186].

PAM is a 5-DOF robot for torso manipulation, and POGO is a leg robot with 2-DOF per leg. PAM's and POGO's actuators are pneumatic, which cost less than electric motors and have higher power-to-weight ratios [64.185]. The robots' ability to control forces and yield to patients and/or therapists has been tested with unimpaired and SCI participants [64.187]. Of particular note here is the development of an adaptive synchronization algorithm that allows these compliant robots to provide assistance at the right time as the participants varies the timing or size of steps.

Based on the string-puppet principle, the String-Man achieves weight bearing and compliant 6-DOF torso manipulation by means of seven wires and a force sensor on each wire [64.182]. In addition, a control scheme has been designed for the String-Man to control both the zero-moment-point location and the ground reaction force with help of foot force sensors.

Veneman et al. [64.189] developed the LOPES exoskeleton (lower extremity powered exoskeleton) visible in Fig. 64.8. In this system, two horizontal pelvis translations are actuated, while the vertical motion is left free and weight is compensated. Furthermore, the LOPES have three actuated rotational joints per leg: two at the hip and one at the knee. The actuation system for hip and knee flexion/extension [64.183] combines Bowden cables with series elastic actuation. The Bow-

den cables allow the motors to be mounted remotely in a fixed position, thus reducing the mass to be moved on the exoskeleton links. The spring element connecting the Bowden cables with the joint allows the closing of a torque feedback control loop with a position sensor that measures the spring elongation, a concept inspired from the series elastic actuators (SEAs) described by Pratt and coworkers [64.190].

Veneman et al.'s experimental results on LOPES SEAs show that adequate torque control bandwidth was achieved by the prototype of their Bowden-cable-based actuation design [64.183], so that the robot can execute both a stiff, position-dominated robot-in-charge mode and a compliant, low-impedance patient-in-charge mode. Some results on the testing of the LOPES exoskeleton are presented in [64.192–194].

The FET European project *Evolving Morphologies for Human–Robot Symbiotic Interaction* (EVRYON) investigated a novel approach for the design of wearable robots in which robot morphology and control are co-evolved in a physics-based simulation environment to achieve a symbiotic interaction, with useful behaviors (walking patterns) emerging from the dynamic interaction between the robot and the human body. To narrow the search space, an atlas of topologies of robot architectures assisting hip and knee flexion/extension was produced [64.195], showing that only ten topologies are capable of providing independent assistance to hip and knee if the number of robot links is not higher than 4 and only revolute joints are considered. The kinematic structures (morphologies) descending from such topologies do not require the alignment of robot and human joints (nonanthropomorphism), thus possibly shortening calibration time and limiting wearability issues. Among the abovementioned ten topologies, only

Fig.64.8a,b LOPES (lower-extremity powered exoskeleton) device for gait training and assessment of motor function in stroke survivors (after [64.188])

Fig. 64.9a,b EVRYON/LENAR.
 (a) Wearable robot to assist hip and
 (b) knee flexion/extension through
 series elastic actuators (after [64.191])

one allows us to mechanically (intrinsically) minimize unwanted shear forces while keeping encumbrance low. A morphology belonging to this topology class was optimized to minimize reaction forces on the human body [64.196] and to maximize wearability and back-drivability [64.197]. Based on this study, the lower extremity nonanthropomorphic robot (LENAR) [64.191] was developed (Fig. 64.9), incorporating custom-made series-elastic actuators for a robust interaction control [64.198].

A different approach to gait training was taken with the KineAssist device [64.199]. KineAssist (Fig. 64.10) is a motorized mobile platform that follows the patient and therapist as they move overground and incorporates a smart brace that compliantly supports the patient's trunk and pelvis. This smart support is designed to allow the therapist to adjust its stiffness from fully rigid down to fully compliant. Within a safety zone, the fully compliant mode allows patients to challenge the limits of their stability. A compliant virtual wall catches the patients when they lose balance. The location of this virtual wall is also adjustable. The body weight can be unloaded as needed. The main advantage of this system is the possibility for the therapist to work in close contact with the patient while cooperating with the robotic system, which deals with the crucial, basic task to keep the patient stable and safe. From this research platform, HDT Robotics began commercialization of the KineAssist-MX. Actuation and sensors allow interactive force-field environments so that a wide variety of

challenging mobility experiences can be delivered to the user.

Other efforts include *Ferris* and coworkers [64.202], who are developing foot, ankle, knee, and hip orthoses actuated by artificial pneumatic muscles that may possibly be used to assist in gait training. The Rutgers Ankle is a 6-DOF pneumatic system based on a Stewart Platform that allows exercise of the ankle [64.203]. Also in the United States, Agrawal's group proposes the use of gravity-balancing leg orthoses for people with gait impairments to practice walking [64.204]. Their designs allow the orthoses to passively support the gravity torque required at the patient's joints. This approach would have the advantage of being safer than powerful robots for clinical use. They have also extended their design

Fig. 64.10 KINE ASSIST for unobtrusive support to patients, allowing them to walk on their own, or with variable levels of support (after [64.200])

Fig. 64.11 Active leg exoskeleton (ALEX) to supplement traditional rehabilitation therapy (after [64.201])

walks in a circle [64.206]. Banala et al. developed the treadmill-based rehabilitation robot ALEX [64.207], as seen in Fig. 64.11. In this system, hip and knee joints are actuated in the sagittal plane while hip abduction/adduction and ankle motion are spring-loaded. More details and further examples of robotic systems for walking therapy are reported in [64.208].

Other Robotic Movement Therapy Approaches

As reviewed earlier, most of the work to date in robotic therapy devices has focused on robots that are attached to patients to assist them in practicing reaching or walking exercises. Other early proposals for using robots for movement therapy included using two planar robot arms to carefully control continuous passive motion of the knee following joint surgery [64.37], and using a multiaxis robot arm to place targets for patients doing reaching exercises [64.209]. An emerging approach toward robotic movement therapy is to provide the therapy at a distance, in a form of telerehabilitation, in order to improve accessibility to the therapy [64.81, 123, 210]. Non-contacting, socially assistive robots, as reviewed in Chap. 73, may play an important role in motivating and monitoring therapy.

to include actuators with reduced torque requirements [64.205]. A robot has been used to provide graded body weight support as a patient who cannot bear full body weight because of a medical problem

64.3 Aids for People with Disabilities

Enabling technologies assist people with disabilities to achieve a quality of life on a par with able-bodied individuals through increased functional independence. The main issue with most such technologies is that disability has a highly individualized impact: a solution for one person will not work for someone else, even if their disabilities appear clinically similar.

64.3.1 Grand Challenges and Enabling Technologies

The more a disability impacts function, the more costly the technical intervention tends to be, since the consumer market cannot benefit from economies of scale if each solution must be individualized. As an extreme example, an electric wheelchair with individualized padding, motorized recliner, and customized joystick control costs as much as a mass-produced mid-sized automobile, but has a fraction of the electronics, robustness, and functions. A grand challenge for assistive, enabling technologies is to find a means to make mass-personalization possible, as it has been in the automotive industry, for example. One component is designer focus. If we can re-badge *assistive technology* as *design for well-being products*, the change in focus from

fixing people to improving their quality of life will have the effect of mainstreaming disability itself so that manufacturers of consumer equipment tend to develop products that can explicitly accommodate a much wider range of functional abilities and therefore provide benefit to a larger, overall less-able, consumer base. As the average age of the baby boomers climbs into retirement years with significant disposable income, this segment will compel the market into providing better solutions to their well-being needs.

Another grand challenge is robotic autonomy. Especially for persons with reduced communication, physical and/or cognitive abilities, a rehabilitation robot will need to have sensory (e.g., vision, auditory) and motor capabilities, combined with its own software processing capabilities (also termed artificial intelligence), that make it a sufficiently safe and capable system to coexist with and benefit humans. This challenge will to some extent be dependent on continuing increases in computer-processing power, and also specifically dependent on the algorithmic developments that issue from the community of robotics researchers.

For instance, several advanced navigation assistive tools for blind and visually impaired persons have

been developed by exploiting knowledge and technologies directly derived from research on autonomous robot navigation; as a sample, *Borenstein and Ulrich* in 1997 developed the GuideCane [64.211], an intelligent cane, based on ultrasound proximity sensor technology, which was designed to help blind or visually impaired travellers to navigate safely and quickly among obstacles and other hazards faced by blind pedestrians [64.212].

Research on robotic aids (namely *physically assistive robots* or, also, *contact assistive robots*) has so far primarily targeted persons with mobility and manipulation limitations, rather than children and adults with cognitive impairments [64.213, 214]. However, increases in the prevalence of cognitive impairments related to aging will make the latter focus increasingly important. *Socially assistive robots*, also named *contactless assistive robots*, are emerging assistive systems that focus on helping human users through social rather than physical interaction (see Chap. 73 for more details on socially assistive robots). Research has been limited to the mobility focus due to the difficulty of designing and developing intrinsically safe robots that can coexist with people and exhibit a certain amount of autonomy while performing useful work. Robots, therefore, today rely on user vigilance and explicit control to be safe. If the user does not have the cognitive capacity to evaluate a robot's safety situation or the ability to communicate efficiently, then the positive value of a function-enhancing robot is nullified by the harm that it could inflict on the user or bystanders. Coupled with the fact that the design of interfaces to personal robots is still in its infancy, a challenge for robotic aid developers is a significant improvement in intrinsic safety without a decrease in function (strength, speed, etc.) from what is typical today in industrial robotics.

To address some of these challenges, the US government, through NSF, NIH and other federal agencies, in 2011 issued a call for a \$ 50 million per year, 5-year program called the National Robotics Initiative (NRI) [64.215]. The realization of co-robots acting in the direct support of individuals and groups. A substantial amount of this funding is focused on healthcare of the future.

Disabilities and Functional Limitations Served by Robotic Aids

Assistive robots have been designed for people who have become severely disabled as a result of, for example, muscular dystrophy or a high-level SCI, for children who have CP, and more generally for anyone who lacks the ability to manipulate household objects. A market research study conducted 10 years ago, specifically for rehabilitation robotics clients, con-

servatively projected a US market of 100 000 people [64.216]. With the incidence of disability increasing exponentially, and the niches that robots can fill in rehabilitation applications multiplying with advances in robotics and rehabilitation science, it is clear that the market for rehabilitation robotics can only continue to increase.

Human–Robot Interface Design for Assistive Robots

A fundamental difference between using industrial and assistive robots is the interface required to command, control, and ultimately benefit from them. An industrial robot commonly has a combination of a manual controller and a programming language interface to allow an operator to teach a robot where to go and to enter the specific motion, grasping, tool changing, and error-recovery steps it must follow repeatedly in its factory automation scenario. An assistive robot, on the other hand, typically has three main differences and challenges:

1. The operator is not by definition a roboticist or engineer, so the interface must make accessible all the functions of the robot to allow its user to complete the required tasks.
2. The user of a rehabilitation robot is, by definition, a person with a disability, which means that physical, sensory, communication, and/or cognitive limitations in accessing the commands and controls of a robot need to be handled on a systems level by the designers of robots and their interfaces, with critical attention to universal design principles, and
3. All rehabilitation robots require individualization of the interface to each user by the engineering and therapy professionals in charge of prescription and fitting, since disabilities vary considerably in how they restrict adaptability to standard configurations [64.217].

Interfaces of assistive robots consist of the software and hardware components conceived to enable a person with a disability to interact with an assistive device, thus tapping into residual communication capabilities of each user. For example, many people with tetraplegia retain the ability to move a hand, arm, foot, or the head in a repeatable, even if range-limited way, and possibly even in two axes, such as forward/backward and left/right. With a proper placement of pushbuttons, a joystick, or noncontact position measurement device, a rehabilitation engineer and therapist can develop a custom solution for each of their clients with disabilities to control a wheelchair computer and robot. In addition, adaptive hardware and software for controlling a computer, such as head-position cursor control,

eye-trackers, speech recognition systems, trackballs and special keyboards, can be used to provide access to computer-based robot functionality.

Even more important than for able-bodied computer and robot users, redundancy in input modality is important for persons with disabilities to prevent a system from becoming inoperable due to a simple interface malfunction or calibration problem. Providing two means of creating a mouse-click action (for example, a separate button placed next to a cursor-control trackball, as well as dwell time on a software *button* on-screen), even if one is inherently slower than the other, allows continued and uninterrupted use of the computer without outside assistance even if one of the two fails.

For therapy robots, physical interfaces resemble those for physical and occupational therapy equipment, in general, and have a commonality with sports equipment interfaces as well, with adjustable hook-and-loop-type straps, heat-formable plastic cuffs, soft rubber, foam-based materials, and durable coverings for abrasion resistance and long wear. After a session or two for fitting and adaptation, a person using a therapy robot can often use the same interface for a long period of time.

In summary, the keys to interface design are customizability, individualization, functional redundancy, adaptability, and patience in getting the interface to a comfort and functional level appropriate for the effective use of the robot.

64.3.2 Types and Examples of Assistive Rehabilitation Robots

As mentioned in the Introduction, assistive robots can be divided into three main categories: manipulation aids, mobility aids, and cognitive aids. Each can be subdivided as follows. Manipulation aids are commonly divided into fixed, portable, and mobile subtypes. Mobility aids are divided into electric wheelchairs with autonomous navigation features and smart walkers. Cognitive aids are divided into communication aids such as pet robots and autonomous caretaker robots. These categories are introduced below, and representative systems that have undergone scientific user studies or are commercial products are presented (Fig. 64.12a–c). Other examples are mentioned in Sect. 64.1.3.

Manipulation Aids: Fixed-Base

Common robots of this type are ADL and vocational manipulation aids and kitchen robots. In the United States, the professional vocational assistive robot (ProVAR) is a research prototype based initially on a PUMA-260 robot arm mounted on a 1 m

Fig. 64.12a–c Workstation-type robots: (a) AfMaster, developed by the French Muscular Dystrophy Association, (b) ProVAR, developed at the VA Palo Alto Rehabilitation R&D Center, and (c) Handy-1, developed by RehabRobotics, Ltd. (UK)

transverse overhead track that allows the robot to manipulate objects and operate devices on side shelves and the table-top, bringing objects (like a drink of water or throat lozenge) to the robot's operator. The interface is via a JAVA/VRML plug-in to a common Internet browser, delivering high-level control to disabled office workers in a conventional pull-down menu and a control screen interface [64.27, 218]. This system and its predecessor DeVAR have been field tested by over 50 subjects at 5 rehabilitation clinics to assess feasibility and acceptability [64.219, 220]. At a cost of over US \$ 100 000 currently, there are currently no plans for eventual product introduction.

In the EU, following a development path parallel to ProVAR's, there is the AfMASTER/RAID workstation, whose concept, instead of being built into a workstation, includes a 2 m × 3 m robot work area in the user's office to store objects and place appliances, next to the user's own office space. The system has been developed

over a 20-year span and was briefly in limited production [64.29] but is no longer offered for sale.

The kitchen robot, Giving-A-Hand, developed at the Scuola Superiore Sant'Anna in Pisa, Italy, is a low-degree-of-freedom device for mounting on the front rail of a kitchen counter and able to move food containers to and from appliances, such as refrigerators and ovens [64.221]. With an integrated control system, it can also make use of the internal controls of the devices to, for example, set cooking times and open doors.

The UK-developed Handy-1 is a domestic robot with 3-DOF designed for one-switch operation by persons with CP [64.30]. Originally designed to allow a person to eat a meal one bite at a time, its application areas have been extended to face hygiene and cosmetics. A commercial product selling for about US\$ 6000, it has been a commercial success due to its simplicity and application focus. An even simpler feeding robot, the UK's electric Neater Eater [64.20] is for sale worldwide at about US\$ 5000, and is designed for eating only.

In [64.222], an overview of manipulation robotic aids is provided. They are classified through five criteria, based on robotic arm usage scenarios and surveys. In particular, new assistive manipulators have recently been developed that address interaction safety as a priority criterion in their design. Take for instance JACO [64.223], iARM [64.224] and RAPUDA [64.225] as examples of robot arms achieving safety by limiting the performance of the robotic arm in terms of arm-movement speed and acceleration in space, end-effector force and maximum possible payload. Examples of robots addressing safety through backdrivable joints (as in the WAM Arm [64.226]) or through active impedance control (as in KARES II, WAM Arm, Elumotion RT2 [64.227], DLR LWR-III [64.228]) can also be mentioned.

While a robot conventionally connotes a stand-alone system with some automation features, a smart bed and a smart home can legitimately be termed robots since they sense and act with motors under the shared control of its human users and its real-time software programming. Smart beds, such as SleepSmart measures body position and temperature, as well as trends and anomalies over the course of a night. Restlessness can be measured, and bed geometry (tilt of bed segments) and ambient conditions (light, temperature, sounds) can be adjusted according to presets and preferences [64.229].

Smart homes, such as the AwareHome domotic environment at Georgia Tech, NL-iRV, and the University of Tokyo [64.230], provide integrated climate, security, lighting, entertainment and transport assistance, which is enabling especially to persons with severe functional disabilities. Coupled with health care-related

functionality (following section), these robotic homes can allow a person with a cognitive or physical disability to control many ADL functions and live safely through monitoring.

Manipulation Aids: Wheelchair Manipulator Arm Systems

A need for electric wheelchair users is the manipulation of objects while navigating a home or a public place such as a restaurant or grocery store. The assistive robot service manipulator (ARM) (Exact Dynamics, Netherlands) – previously known as MANUS – is a commercial robot arm that can be attached to an existing wheelchair to the side of the lap tray and controlled by the wheelchair's own joystick or a number pad [64.23, 231] (Fig. 64.13). The robot has undergone numerous user studies with persons who have muscular dystrophy, a high-level SCI or CP. Worldwide, this is currently the only commercial rehabilitation robot arm that can be prescribed by a physician and that is reimbursed by a government health care system.

Weston [64.232] and Bridgit [64.233] are two wheelchair manipulator arm systems addressing the issue of interaction safety in their design, as for some of the manipulation aids with a fixed base presented earlier. Weston uses low-power motors in order to statically and intrinsically limiting the arm's acceleration, force and payload. Bridgit is a manipulator arm placed

Fig. 64.13 Wheelchair manipulator robot MANUS developed at the Rehabilitation R&D Center, Hoensbroek, and marketed by Exact Dynamics (The Netherlands)

on a wheelchair on a rail system. The robot moves over the rail system resulting in optimal positioning for each task. The rail system also allows for easy docking of the robot either on the back or front side of the wheelchair when not in use.

Manipulation Aids: Mobile Autonomous Systems

The most commonly thought-of form of a robot is that of an autonomous, mobile system with arms, having sensory-motor functionality similar to that of a human being, while serving people in performing menial physical tasks. This Handbook's chapter on Humanoid Robots explores the domain as well (Chap. 67). Since locomotion is a key requirement for Humanoid robotics, other robots with wheeled bases have been developed before the first walking robots were invented to explore more applied domains with more short-term usefulness. In film, robots such as Star Wars' R2D2 have made this form factor commonly known around the world. More recently, real robots such as the Help-Mate [64.234] have been employed in US hospitals as fetch-and-carry robot orderlies, using floor maps and short-range ultrasonic sensors for navigation and obstacle avoidance. The Italian MovAid research robot platform [64.235] (in Fig. 64.14) adds manipulation and vision to these capabilities to navigate in home-like environments to provide object manipulation and device operation to individual users. The European project Robot-Era [64.236] is following up these developments with a specific target on the needs of aging population. The German Care-O-bot [64.237] has explored advanced navigation and sensing in a wheeled robot that can also be used as a physical support to people requiring mobility and stability assistance. It has also doubled as a mobile kiosk, moving around a trade show floor and delivering information to attendees. In [64.238] a case study of a personal robot based on the PR2 Humanoid robot (Willow Garage, Menlo Park) is presented. The approach pursued consists of developing a diverse suite of open-source software tools that blend the capabilities of the user and the robot in order to enable the assistive mobile manipulators to move in real homes and work with people with disabilities.

Mobility Aids: Wheelchair Navigation Systems

A critical function for people who use electric wheelchairs for their mobility impairment and who in addition have communication or cognitive disability is semiautonomous navigation assistance (Fig. 64.15).

Add-ons to commercial wheelchairs have been developed by numerous research groups for this service. Such wheelchairs are typically referred to as smart or intelligent wheelchairs. As proposed by *Simp-*

Fig. 64.14 MovAid (after [64.239])

son [64.240], smart wheelchairs can be classified by form factor: early smart wheelchairs were mobile robots with added seats. The vast majority of smart wheelchairs developed until 2005 were based on heavily modified, commercially available, powered wheelchairs. Only a smaller fraction of them were

Fig.64.15a,b Wheelchair navigation aids: (a) Wheelseley and (b) Hephaestus

equipped with *add-on* units that could be attached to and removed from the underlying powered wheelchair.

The NavChair [64.241] was one of the first to demonstrate robust wall-following, door passage even with narrow doorways, and speed adaptation to people walking in front of the wheelchair, all using only short-range ultrasonic and other sensors, but not vision. The Hephaestus [64.35] is a next-generation system made specifically as a commercial accessory for a variety of wheelchair brands, tapping into the joystick controller and power system. The *Wheelseley* [64.242] and KARES [64.33] robots have explored similar functionality using a vision system for scene analysis and way-finding.

More recently, the CanWheel project team developed an intelligent wheelchair system called NOAH [64.243, 244]. The system has three main capabilities: collision avoidance, infer the user's goal location/activity and provide automated reminders, provide navigation assistance using prompts. The rationale

for proposing such solutions is to enhance mobility and to help improving the quality of life of older adults with cognitive impairments, while simultaneously reducing the burden on caregivers.

In 2013, How et al. [64.245] proposed a new intelligent wheelchair system (IWS) with anticollision and navigation features. User trials showed the IWS's potential to improve powered wheelchair safety and subjective usability.

The IntellWheels [64.246] project proposes a modular platform based on a multiagent system paradigm for the development of intelligent wheelchairs based on commercial products. Within this project, promising results have been achieved on the development of adapted control methods for CP users of an intelligent wheelchair. Experiments demonstrated that users felt that they had better control over the wheelchair movement when using shared control rather than manual or automatic control modalities [64.247].

The iBOT [64.248–250] is a powered wheelchair for persons with mobility impairment developed by Kamen, in a partnership between DEKA and Johnson & Johnson's Independence Technology division. Research on iBOT was discontinued in 2009. The iBOT features self-balancing technology, which allows users to go up and down staircases, to navigate on uneven terrain and to *stand* at an eye level with people walking nearby.

Mobility Aids: Walking Assistance Systems

A third type of mobile robot for stability assistance has the peculiarity that it is underactuated and has similarity with the *co-bot* concept, in that the wheels are not driven, but are actively steered and braked (Fig. 64.16). The concept of collaborative *co-bots* was originally introduced by Colgate et al. for robots operating in di-

Fig.64.16a–c Human assistance robots: (a) Care-O-bot, developed by the Fraunhofer Research Institute (Germany). (b) Helpmate by Transitions Research Inc., USA. (c) Pam-Aid (aka Guido), developed in the UK

rect physical interaction with a human factory worker, handling a shared payload. They are a marked departure from autonomous industrial robots, which must be isolated from people for safety reasons [64.251, 252]. Co-bots interact with people by producing software-defined *virtual surfaces* which constrain and guide the motion of the shared payload, but add little or no power [64.253]. Today, cobots are being prototyped in the rehabilitative and assistive context, e.g., for bed to chair/wheelchair transfer or table-top upper limb, stroke rehabilitation at home. For example, the Pam-Aid [64.254] looks like a closed-front walker on wheels and has bicycle-type handlebars. The person walking behind the device turns the handlebars, causing the wheels to turn in the correct direction. If the ultrasonic sensors detect an obstacle in front of it, the brakes prevent the user and device from colliding with it. The Care-O-bot (see earlier) designed originally as a mobile autonomous robot approximately human size, has a similar set of handlebars, similar to the Pam-Aid it, so it can be used as a smart walker. The larger mass of the Care-O-bot, however, requires it to be motorized.

Mobility Aids: Exoskeletons

Exoskeletons for walking assistance are similar to robots used in treadmill-based environments for rehabilitation. These systems are portable and autonomous and intended to be used in daily life scenarios. Several review papers have been recently published [64.255–257] on this topic.

In the framework of NIST's Advanced Technology Program, Ekso Bionics (Berkeley, USA) developed the Ekso device [64.258] (Fig. 64.17). This robot has been developed for people with lower extremity weakness or paralysis due to neurological disease or injury (e.g., spinal cord injuries, multiple sclerosis, Guillain-Barré syndrome) and it has an almost anthropomorphic structure with hip and knee joints actuated in the sagittal plane. The ankle joints are not actuated but are compliant in the sagittal plane and locked out in the other DOFs. Testing of the device has included paraplegic persons with complete or incomplete paralysis [64.259] and chronic stroke patients [64.260].

The ReWalk was developed by Argo Medical Technologies [64.261]. It is actuated by DC (direct current) motors at the hip and knee joints in the sagittal plane, while the ankle joint is not actuated. The system is designed with a remote controller that can be used to change the motion mode (e.g., ground walking, climbing stairs). A posture sensor on the torso detects the upper body movement of the user and estimates motion intention. The wearer also has to use crutches for stability and safety reasons. The system is undergoing

Fig. 64.17 Ekso Bionics exoskeleton for paraplegics (after [64.258])

clinical trials among other research centers at Moss-Rehab (Philadelphia, USA) and at the Centro Protesi INAIL di Vigorso di Budrio (Bologna, Italy) on paraplegic subjects. The device is now available on the market in two versions: the ReWalk-Rehabilitation for institutional use and the ReWalk-Personal developed for daily use (Fig. 64.18).

Sankai's group at the University of Tsukuba (Japan) developed an exoskeleton both for performance augmentation and for rehabilitation and assistance [64.263, 264]. The current version, HAL-5, powers the flexion/extension of hip and knee via DC motors while ankle dorsi/plantar flexion DOF is passive. The HAL-5 system (Fig. 64.19) integrates a number of sensors: skin-surface EMG electrodes placed below the hip and above the knee on both the anterior (front) and posterior (back) sides of the wearer's body, potentiometers for joints angles measurement, ground reaction force sensors, a gyroscope and accelerometer mounted on the backpack for torso posture estimation. HAL-5 is currently commercialized by the spinoff company Cyberdyne (Tsukuba, Japan). To date, it appears that no peer-reviewed, quantitative results have been published

Fig. 64.18 ReWalk computerized exoskeleton (ReWalk Robotics, Inc., USA; after [64.262])

on the effectiveness of the exoskeleton for the improvement of walking functions.

The Vanderbilt powered orthosis [64.265] is a powered lower limb exoskeleton intended to provide gait assistance to individuals suffering from spinal cord injury by providing assistive torques in the sagittal plane for both the hip and knee joints. It includes neither a portion that is worn over the shoulders, nor a portion that is worn under the shoes. Each joint is powered by a brushless DC motor. The orthotic is intended to be worn together with a standard ankle-foot orthosis, which provides support at the ankle and prevents foot drop during swing. In order to demonstrate its ability to assist walking, the orthosis was experimentally tested on paraplegic subjects. Experimental results indicate that the orthosis is capable of providing a repeatable gait with knee and hip joint amplitudes that are similar to those observed during non-SCI walking.

Fig. 64.19 Robot suit HAL-5 designed by Japanese robotics firm Cyberdyne

REX, produced by REX Bionics (Auckland, New Zealand), is an anthropomorphic lower body robot designed for sit-to-stand, stair climbing and overground walking, without the use of crutches. The system does not use sensors to detect the intention of the user but rather it uses a joystick as its interface. The system has been tested with healthy subjects, and for sit-to-stand of wheelchair users [64.266].

Cognitive Aids

There has recently been increased interest in using robots as motivational and educational agents during rehabilitation therapy. This approach typically involves small, pet-like, toy-like, approachable devices that do not physically interact with the patient, but exist primarily to engage the patient in an affective way that promotes personal health, growth, and interaction. For more information, please see Chap. 73.

64.4 Smart Prostheses and Orthoses

In 2005, the Defense Sciences Office (DSO) of the US governmental research agency DARPA launched a program to revolutionize prosthetics in a four-year timeframe. According to the agency website, this program will:

deliver a prosthetic arm for clinical trials that is far more advanced than any currently available. This device will enable many degrees of freedom for grasping and other hand functions, and will be rugged and resilient to environmental factors. In 4 years, DSO will deliver a prosthetic for clinical trials that has function almost identical to a natural limb in terms of motor control and dexterity, sensory feedback (including proprioception), weight and environmental resilience. The four-year device will be directly controlled by neural signals. The results of this program will allow upper limb amputees to have as normal a life as possible despite their severe injuries.

64.4.1 Grand Challenges and Roadblocks

This program announcement lays down the grand challenge for prosthetics research in an ambitious timeframe: develop an artificial limb that has function and durability at least as good as a natural limb. There are several roadblocks to meeting this challenge. First, providing an intuitive way for individuals to control and coordinate multiple joints of a robotic limb is challenging. Second, robots do not yet match the human arm in terms of the combination of range of force, weight, and duration of use with a portable power source. Third, human limbs are rich with tactile and movement sensors. Installing artificial sensors on a robotic limb, and then returning information from those sensors in a way that is usable by the user is challenging. Thus, solving the grand challenge will require better sensory-motor interfaces for prosthetic limbs, as well as lighter, stronger actuators, and better power sources.

Substantial progress has recently been made in improving sensory-motor interfaces for prosthetic limbs, and this progress is the focus of this section. For the current state of robotic actuators that could be used in prosthetic devices, the reader is referred to Chap. 77 on Neurorobotics. For an overview of the design of conventional prosthetic hands and arms, the reader is referred to [64.267].

64.4.2 Targeted Re-Innervation

Standard prosthetic arms and hands are commonly controlled with a cable drive or by electromyogram (EMG)

signals from residual muscles. For example, to open and close an artificial hand, one common technique is to place a Bowden cable around the shoulders in a harness, and connect the cable directly to the artificial hand. The user can then shrug the shoulders to move the cable and open and close the hand. Alternately, electrodes can be placed on a muscle in the residual limb or on the user's back, for example, and then used to control a motor on the artificial hand. The cable technique has the advantages of simplicity, and of having the property of extended physiological proprioception (EPP), which refers to the fact that the grip force is mechanically transmitted back to the user's shoulder muscle force sensors so that the user can gauge the strength of the grasp. Because of their simplicity and EPP, cable drives (or body powered prostheses) have been more popular than myoelectric (or externally powered) prostheses. However, the body-powered technique is amenable to controlling only one degree of freedom at a time, although chin switches, for example, can be used to switch between degrees of freedom in a somewhat cumbersome way. The myoelectric approach can be used to control multiple degrees of freedom, but such control is nonintuitive and cumbersome. Also, multiple control sites for reading out EMG are not available for people who have lost their entire arm. Thus, prosthetic control systems are typically limited to one or two degrees of freedom, while functional arm and hand movement benefits from at least four degrees of freedom (three to position the hand, and one to open and close it).

Kuiken et al. [64.268] recently developed a novel approach to improving control of a multijointed prosthetic arm. In this targeted re-innervation technique, they re-routed the nerves that previously innervated the lost limb to a spared muscle, and then read out the user's intent to move the limb using electromyography at the spared muscle. They demonstrated this technique in a bilateral shoulder disarticulation amputee who had lost both of his arms in an electrical power accident. They took the residual brachial plexus nerve for the left arm, which normally innervates the left elbow, wrist, and hand, and moved it to the pectoralis muscle. The subject could still contract his pectoralis muscle, but this muscle was no longer useful to him since it used to attach to his now-missing humerus. A surgeon dissected portions of the nerve associated with different muscles in the elbow, wrist, and hand, and innervated three bundles of the pectoralis muscle. After three months, the nerve re-innervated the bundles so that the patient could cause the bundles to twitch by trying to bend his missing elbow, for example. Surface EMG electrodes were

placed over the bundles. Then, when the user wished to open his hand, for example, a pectoralis muscle bundle contracted, and this contraction was detectable with the EMG electrodes. The EMG signal was in turn used to control the hand motor of the prosthetic arm. The net result was that the user could will his different (missing) anatomical joints to move, and the corresponding joints on the robotic arm would move. He could simultaneously operate two joints, such as the elbow and the hand. The user became able to do tasks that he was not able to do before with his conventional myoelectric controlled arm, such as feeding himself, shaving and throwing a ball. A secondary remarkable finding was that the sensory neurons in the re-routed nerves re-innervated sensors, so that now when the person's chest is touched, the person perceives it as a touch to his missing limb. This sensory re-innervation could possibly be made into an interface to provide tactile sensation from the artificial limb. These findings were recently confirmed in another person who received targeted re-innervation [64.269].

64.4.3 Neural Interfaces for Limb Prosthetic Devices

Neural interfaces provide an interesting and challenging solution to retrieve the natural way of interfacing the human nervous system to prosthetic artifacts. They are systems capable of recording either invasively or noninvasively the electrical activity of peripheral nerves as well as of the brain cortex. It has also recently been shown that the direct electrical stimulation of a residual peripheral nerve can provide usable information regarding force to a person with an amputation [64.270], thus paving the way for bidirectional neural interfaces capable of restoring both efferent and afferent information flow to/from the prosthesis. Recently, thin film intrafascicular electrodes implantable in peripheral nerves have been developed [64.271], and successfully validated in 2008 in Italy at Campus Bio-Medico University of Rome on a human amputee [64.272] within the LifeHand project, a cluster of European and Italian research actions focused on neural interfaces for prosthetics (Fig. 64.20). In 2013, a second round of experiments in Italy demonstrated the possibility of delivering physiologically appropriate (near-natural) sensory information to an amputee during the real-time decoding of different grasping tasks to control a dexterous hand prosthesis by stimulating the median and ulnar nerve fascicles using transversal multichannel intrafascicular electrodes, according to the information provided by the artificial sensors from a hand prosthesis [64.273]. The results also demonstrate that the subject was able to identify the stiffness and shape of

Fig. 64.20 LifeHand aims to create a completely implantable prosthesis system, richly sensorized and controlled through the patient's nervous system, with a dexterity comparable to a natural limb (courtesy of Campus Bio-Medico University Rome, Italy)

three different objects by exploiting different characteristics of the elicited tactile sensations. These results are in line with earlier studies which outlined the importance of restoring tactile feedback on a prosthetic device, such as the one proposed by Meek et al. in 1989 [64.274].

Today the above mentioned approach is trying to be extended on lower limb prosthetics as well. Herr et al. a MIT pioneered a new class of bio-hybrid smart prostheses and exoskeletons [64.275] aiming at improving the quality of life of people with physical challenges. Some of these devices are now commercialized by a spin-off company, BiOM. For instance, a computer-controlled prosthesis called the Rheo Knee [64.275] is outfitted with a microprocessor that continually senses the joint's position and the loads applied to the limb. A powered ankle-foot prosthesis emulates the action of a biological leg to create a natural gait, allowing amputees to walk with normal levels of speed and metabolism as if their legs were biological [64.275].

There has also recently been progress in decoding movement-related signals in real-time directly from the brain (see the cover story and related articles in *Nature* of 13 July 2006 [64.276]. The first of several recent human volunteers, a person with tetraplegia due to SCI, has received a BrainGate electrode array implant, and has been able to control the movement of a cursor on a computer screen [64.277]. Noninvasive systems operate by recording brain activity from the outside of the skull via well-known clinical noninvasive diagnostic devices [64.278] such as electro-encephalogram (EEG). Individuals have been demonstrated to be able to learn to control the amplitude of the EEG signal as a function of time, or the amplitude of specific frequency components of the EEG signal, with a moderate amount of practice (several hours to several days). The level of control is sufficient to operate a typing program on a computer, or to control the movement of a cursor to multiple targets.

In summary, given the significant progress observed in the last decade, it appears that future control systems for smart prosthetics and orthoses will have the option to rely on direct interfaces to the brain, which should allow control of multiple joints through thought alone. The initial work on both targeted re-innervation and brain-machine interfaces to the PNS or to the CNS has allowed three to 4-DOF of control in a naturalistic manner and elicitation of some sensory feedback, which is an advance over conventional prosthetic control techniques.

64.4.4 Advances in Neural Stimulation

Functional neural stimulation techniques (FNSs) seek to electrically stimulate the residual nervous system to re-animate the limbs. FNS for standing, walking, reaching, and grasping has been demonstrated, but these techniques have met with limited commercial success because of a combination of factors, including the ease of use of systems that use surface electrodes, duration of use before fatigue, risk from implantation and complexity of the associated control problems.

Two research lines are being pursued to help move the FNS field forward. The first one focuses on hardware innovation. A good example is the BION, an injectable stimulator the size of a very large grain of cooked rice [64.279], which can be inserted without surgery (using a large-gauge needle) and is robust and resistant to infections. The second research line aims at stimulating the control circuits in the nervous system rather than individual muscles. For example, it has been shown that locomotor-like movements can be eliciting in multiple muscles of the cat hind limb by stimulating regions of the spinal cord directly [64.280].

64.4.5 Embedded Intelligence

Recent robotics-related advances for prosthetic legs have included embedding microprocessors and passive braking systems into artificial knees, so that the knees can, for example, be made relatively stiff during the stance phase of gait, and free to move during the swing phase of gait [64.281]. The first microprocessor knee introduced was the Ottobock C-Leg (Germany), introduced in 1999. The C-Leg uses a servomotor to adjust valves to hydraulic pistons. The rechargeable battery lasts about 24 hours. The pattern of resistance throughout the gait cycle can be adjusted for each user. A dramatic example of the benefit of the C-Leg is the story of a man who made it down from the 70th floor of the World Trade Center on 9/11/2001 with only minor bruising to his residual stump [64.282]. Other microprocessor-controlled knees are the endolite adaptive prosthesis, which uses pneumatic and hydraulic valves, the Rheo Knee (Össür Hf, Iceland), which uses magneto-rheologic fluid to vary the knee impedance and the Intelligent Prosthesis.

The first powered knee that can generate power, rather than just dissipate energy, is currently being commercialized by Össur as the Power Knee. The system combines an electromechanical power source that will be controlled with input from sensors on the sound leg shoe. Initial reports suggest that this is the first knee that allows the user to walk up stairs with a step-over-step pattern.

64.5 Augmentation for Diagnosis and Monitoring

A critical aspect of rehabilitation is health maintenance with age-related or degenerative functional decline and after a medical intervention. In-home diagnostic equipment, devices worn on or in the body for vital signs monitoring, tele-health services, and institution-based monitoring automation are all examples of systems be-

ing developed to improve the quality of life for both persons at risk and their caregivers. Institutional systems of this nature, more properly part of the field of clinical engineering, are incorporating more robotic, networked and autonomous devices to take more accurate diagnostics, provide better information to physicians and

provide faster alerts. Key enabling technologies in this field are advanced materials and nanotechnologies.

64.5.1 Grand Challenges and Enabling Technologies

For all devices that are worn on the body, the interface must be skin compatible. A grand challenge for this field in the near-term is the better incorporation of active and sensing elements with textiles. Several prototype sensor shirts show promise, but rehabilitation will have a much richer toolset for diagnosis and monitoring with advances in this area. Nanotechnology, an enabling technology for the longer term, has the promise to miniaturize virtually everything mechatronic that is currently macroscopic. Injected devices, such as nano-robotic drug dispensers and clot-busters will aid in rehabilitation.

64.5.2 Smart Homes for Health Care Monitoring and Care

A special class of fixed-station rehabilitation robots is an automation system designed to provide a safe environment to assist and monitor a person with a disability living at home or in an institutionalized setting such as an assisted living facility or nursing home.

Smart Nursing Home Automation

An assisted living, hospice, or nursing care institutional facility will include residents who have mild to severe cognitive impairment in addition to physical disabilities. The facility may have zones to separate residents who have different levels of dependency since the architectural, monitoring and personnel needs are different. To better serve residents and guests, to optimize function and to minimize cost, only the areas for persons with high dependency have a 24 h staffed vital signs monitoring and alert capability, for example. Facility care is highly staff-intensive, though automation through diagnostic vital signs monitoring, electronic surveillance, and patient tracking continue to improve safety and efficiency. Robotics and automation are beginning to find applications in the physical tasks associated with patient care, therapy and oversight. Some examples are described below.

Examples of the State of the Art

Wandering, especially at night, is a significant problem for institutional facilities with ambulatory residents who are cognitively impaired. Simple architectural modifications include painting the hallway in front of doors black to make them look like deep holes. An automated voice system triggered by a motion detector to

say *Go back to bed* is effective, but not fool-proof, either. Resident detection systems based on ID badges with embedded RFID chips that can be sensed in a hallway work, but only if the resident is wearing it. A robotic sentry system, including mobile platforms to aid in solving this problem, especially at night, has not yet been developed.

A serious rehabilitation issue in institutionalized facilities is the transfer of residents from bed to wheelchair and other surfaces. A number of manual, electric, and robotic devices have been developed to assist the nursing staff to safely transfer residents and patients who may be significantly heavier than they are. This remains an unmet clinical need, though not for lack of innovative attempts [64.283, 284].

64.5.3 Home-Based Rehabilitation Monitoring and Therapy Systems

Numerous smart homes have been developed for non-rehabilitation as well as assistive purposes [64.285]. These systems have as their goal the safety of people with disabilities living in the home and communication with caregivers outside of the home. Caregivers can be live-in family or attendants who, even when they are not home, need to be kept informed on the status of the disabled person, as well as clinicians who need to be sent regular vital signs and other medical/therapy reports. In-home systems typically feature the same principal elements:

1. Sensors to monitor both ambient and as people- and object-specific parameters (e.g., person location, stovetop operation); actuators to modify ambient conditions (heat, lighting, sound system, etc.) and operate devices (doors, refrigerator, etc.).
2. A means to network all the sensors and actuators for uni- or bi-directional communication with the host computer. This network can be wireless (e.g., 802.11 g), wired (e.g., coaxial cable), or dependent on an existing network (e.g., signals superimposed on current carried by the electrical mains wiring or phone wiring).
3. A host computer that allows all sensor states to be displayed and actuators to be operated from one or more locations in the home by the inhabitant(s) using common computer I/O devices. Higher order functions are built upon this basic capability.
4. An external network to allow communication with the Internet via phone, cable, satellite or other means. This capability allows for remote monitoring and operation, sending of alarms and discussions with rehabilitation professionals at medical centers.

The host computer software may also have higher order features, for example timers for repetitive actuation of lights and monitoring for anomalous sensor readings (e.g., call security when the smoke detector activates, alert inhabitants with in-home alarm when stove top power is on and no pot is on the stove). More advanced features that involve multi-input and multioutput control and adaptive, predictive, context-aware operation [64.286] are areas of active research, and especially important to the rehabilitation community.

As previously mentioned in this chapter, devices for home-based robot-assisted therapy have been recently developed, and home-based therapy delivered by robotic devices is expected to have a significant growth in the short-medium term.

CBM Motus [64.126] and T-WREX, [64.287, 288], a passive exoskeleton for upper limb rehabilitation now sold by Hocoma AG as ArmeoSpring, are just two examples of systems for home-based therapy described above (Sect. 64.2.3). Another example is the Hand Mentor, which is a device which uses video games and robotics to cognitively involve the patient in his/her rehabilitation [64.289, 290]. The Hand Mentor can be used in the clinic, or taken at home and incorporated into patients' daily therapy sessions to lengthen shortened tissues, facilitate hand opening and closing, and reduce spasticity. It is mainly conceived for stroke patients' rehabilitation and is commercialized by Kinetic Muscles, Inc.

64.5.4 Wearable Monitoring Devices

One component of an automated rehabilitation environment is the subsystem that a person wears to be able to measure, analyze, and communicate physiological signals to an external computer wirelessly. Systems such as the LifeShirt (VivoMetrics, Inc., Ventura) [64.291] have been and are being developed for front-line soldiers and rescue operation personnel whose health may become imperiled when out of touch with and unable to communicate verbally with their base command. For rehabilitative purposes, for example, the Intel Proactive Health Initiative [64.292] is an example of a system that use on-person position and motion sensing to detect potentially dangerous or undesirable situations.

The use of a robot to deliver therapy already enables measuring information on the patient state by exploiting robot sensors and other wearable units, if needed [64.293]. Such capability can be exploited for patient monitoring. A recent work proposed a method for reconstructing the human arm kinematics by resorting to an inverse kinematics technique for redundant robot arms [64.294].

The most significant obstacles to the widespread adoption of these technologies in the short term are cost, false-positive alarms, inconvenience and encumbrance. Advances in micro-electronics, nanotechnologies, software algorithms, and networking capabilities will continue to drive the research and consumer acceptance of this technology sector.

64.6 Safety, Ethics, Access and Economics

Rehabilitation robots interact closely with humans, often sharing the same workspace and sometimes physically attaching to humans, as in the case of robotic movement training devices and prosthetic limbs. Furthermore, the devices are by necessity powerful enough to manipulate the environment or the user's own limbs, which means that they are also often powerful enough to injure the user or another person nearby by colliding with them or moving their limbs inappropriately. Safety is clearly of paramount importance.

A common strategy for ensuring safety is to incorporate multiple, redundant safety features. A device can be designed to be mechanically incapable of moving itself or the user's limbs in such a way as to cause injury. Limits can be placed on the range, strength and speed of actuators so that they can accomplish the desired task but no more. Break-away attachments can be used to attach to users' limbs. Covers can protect the user from pinch points in the device. Redundant sen-

sors can be included, so that if one sensor malfunctions another sensor can identify the malfunction and help safely shut down the machine. Watchdog timers can monitor the health of the control computer. Software checks can limit forces, motions, speeds, and user adjustments to control parameters, as well as check for sensor health and other dangerous situations. Control strategies can be designed so that the device is mechanically compliant, reducing the risk of forcing a limb into an undesirable configuration, or of a high-impact collision. A manual override switch can be incorporated so that the user can shutdown the system. Finally, the user can be instructed on how to safely operate the device and avoid dangerous situations. Safety ultimately depends, however, on careful and rigorous failure mode analysis and remediation by the system designers.

From a system's perspective, when all else fails actively to protect the user, it must be the design itself

that makes the robot inherently unable to injure its user. Part of the solution is in reducing the weight, rounding the surface characteristics, and making appropriate materials choices. The goal of inherent safety, however, is often at odds with high performance and adequate payload for real-life tasks. Recently, several approaches to designing personal robots – in other words – the class to which assistive rehabilitation robots belong – have sought to address both goals by dividing the two tasks of compensating for gravity (arm plus payload) and moving the payload around in space [64.295]. The solution is to provide two actuators per joint on the joints that support the arm segments and payload against gravity: one slow, gear-reduced motor and energy storing device such as a large spring or compressed air volume, and one small, backdrivable motor that provides the power needed to move objects around quickly and precisely. Most robot manipulators have approximately a 1 : 10 (or worse) payload-to-weight ratio. A system with a dual, parallel actuator system that requires only the small, fast actuator to be carried in the arm, leaving the slow energy-storage system on the base and not contributing to the inertia of the arm itself, can lead to a 1 : 1 payload-to-weight ratio more in line with a human's own arm characteristics, and thereby provides a safe yet high-performance solution. An added benefit from this type of arrangement is that the movements of the arm will tend to be more human-like, providing a measure of confidence to the user that the robot is performing properly and moving in a safe way.

Strategies for improving safety have been proposed and methods to assess safety have been developed and adapted for rehabilitation robotics [64.296, 297] based on accepted risk analysis methods. While industrial robots have benefited from ISO user safety regulations since 1992 (ISO 10218), the fundamental issue of human proximity to robots for the personal, service, and rehabilitation sectors has prevented that standard from

being applicable to rehabilitation robots. Currently, a draft of a new *safety requirements for personal care robots* standard, ISO 13482, is under development. Currently, the existing industrial standards, augmented with provisions from medical equipment standards and buttressed by engineering best practices and adherence to professional codes of ethics by designers, have guided rehabilitation robotics designers. Clearly, as products appear on the market and the expected rapid expansion of this sector happens, better regulations and standards must be developed.

Beyond safety, there are other ethical concerns that will emerge as robotics technology becomes more intelligent with advances in cognitive software, more invasive with nanotechnologies and better integrated with human systems through bioengineering advances. Ethicists and roboticists are starting to deal with these issues [64.298, 299], which to date have been the purview of only futurists and science fiction writers. Chap. 80 deals with these issues in detail.

An economic advantage has not yet been demonstrated in a decisive way for most rehabilitation robotics. For example, the therapeutic benefits conferred by robotic therapy devices, and the assistive benefits conferred by wheelchair-mounted robots relative to the devices' cost, have not yet been large enough to cause widespread adoption. Improvements in their efficacy and reductions in their cost will increase their usage. For example, a robotic therapy device that helps people learn to walk after a stroke, in a way that is decisively better than other training techniques, would become widely used very quickly. Likewise, a wheelchair-mounted robot that gives a disabled person a substantial and efficient increase in autonomy at a reasonable cost would also quickly become widely used. An example of a robotics technology that has achieved an attractive cost-benefit ratio and thus is commercially successful is the powered wheelchair.

64.7 Conclusions and Further Readings

Rehabilitation robotics is a dynamic application area because its grand challenges are at the forefront of both robotics and biology research. The ongoing major themes of the field can be summarized as the development of robotic therapy devices, smart prostheses, orthoses, functional aids and nurses that match or exceed the capabilities of their human counterparts. Rehabilitation robotics is also a highly motivating field because the technology developed will directly help people who are limited in major life activities. The field will continue to grow because of the dramatic aging of

the populations of industrialized countries that is just beginning.

The grand challenges of rehabilitation robotics are grounded in the distinguishing features of the field: functional involvement with humans, a physical user interface and behavior that is intelligent, adaptive, and safe. These characteristics require high levels of redundancy, sensory-motor capability, adaptability, and multilevel software architecture. The grand challenges therefore span the domains of electromechanical design, software design, and, due to the applied and in-

nately human-focused nature of rehabilitation robotics, all aspects of user interface design, including physical, communication, learning, emotional, and motivational factors. The first products in this field have come on the market in only the last 15 years; worldwide demographic trends will provide the force to accelerate product development in the future.

For further investigation on rehabilitation robotics, there are three major sources of published information:

1. Books on personal, service and rehabilitation robotics, such as: [64.300–302]
2. Review articles in journals and periodicals, such as [64.303–307] and
3. Articles that deal with individual topics, such as those in the reference list below, and conferences such as ICORR, RESNA, RO-MAN, BIOROB, and AAATE, which are also represented in the reference list.

Cutting-edge research will be reported on the websites of investigators at academic, government and corporate research labs, and it is recommended to start at the sites of the researchers cited in this chapter.

65. Domestic Robotics

Erwin Prassler, Mario E. Munich, Paolo Pirjanian, Kazuhiro Kosuge

When the first edition of this book was published domestic robots were spoken of as a dream that was slowly becoming reality. At that time, in 2008, we looked back on more than twenty years of research and development in domestic robotics, especially in cleaning robotics. Although everybody expected cleaning to be the killer app for domestic robotics in the first half of these twenty years nothing big really happened. About ten years before the first edition of this book appeared, all of a sudden things started moving. Several small, but also some larger enterprises announced that they would soon launch domestic cleaning robots. The robotics community was anxiously awaiting these first cleaning robots and so were consumers. The big burst, however, was yet to come. The price tag of those cleaning robots was far beyond what people were willing to pay for a vacuum cleaner. It took another four years until, in 2002, a small and inexpensive device, which was not even called a cleaning robot, brought the first breakthrough: *Roomba*. Sales of the Roomba quickly passed the first million robots and increased rapidly. While for the first years after Roomba's release, the big players remained on the sidelines, possibly to revise their own designs and, in particular their business models and price tags, some other small players followed quickly and came out with their own products. We reported about these devices and their creators in the first edition. Since then the momentum in the field of domestic robotics has steadily increased. Nowadays most big appliance manufacturers have domestic cleaning robots in their portfolio. We are not only seeing more and more domestic cleaning robots and lawn mowers on the market, but we are also seeing new types of domestic robots, window cleaners, plant watering robots, tele-presence robots, domestic surveillance robots, and robotic sports devices.

Some of these new types of domestic robots are still prototypes or concept studies. Others have already crossed the threshold to becoming commercial products.

For the second edition of this chapter, we have decided to not only enumerate the devices that have emerged and survived in the past five years, but also to take a look back at how it all began, contrasting this retrospection with the burst of progress in the past five years in domestic cleaning robotics. We will not describe and discuss in detail every single cleaning robot that has seen the light of the day, but select those that are representative for the evolution of the technology as well as the market. We will also reserve some space for new types of mobile domestic robots, which will be the success stories or failures for the next edition of this chapter. Further we will look into nonmobile domestic robots, also called smart appliances, and examine their fate. Last but not least, we will look at the recent developments in the area of intelligent homes that surround and, at times, also control the mobile domestic robots and smart appliances described in the preceding sections.

65.1 Mobile Domestic Robotics

The first mention of a domestic cleaning robot dates back to 1985. The device, nicknamed *Robby*, was developed by Hitachi starting in 1983 and officially carried the name HCR-00 (Fig. 65.1). Robby was equipped with a gyroscope to keep track of its position and a rotating sonar scanner for obstacle detection.

65.1.1 Domestic Floor Cleaning

Very similar to today’s cleaning robots described further below, Robby already mapped its environment and used the map for path planning. HRC-00 remained a prototype like its successors HRC-01 to HRC-03.

**First Generation
of Domestic Cleaning Robotics (1985–1999)**
Also in 1985, the Swedish appliance manufacturer Electrolux started the development of a concept vacuum cleaner *Stardust*. The device was equipped with eight fixed sonar sensors and one rotating sensors for obstacle detection. To maintain its orientation Stardust used

an infrared sensor that tracked an infrared light bulb mounted to the ceiling. In 1988 Stardust was presented to the public at Domotechnica in Cologne, Germany, one of the largest fairs worldwide for domestic appliances [65.1].

About five years later, between 1989 and 1991, Panasonic undertook an effort to develop a domestic cleaning robot that led to two prototypes, one of them, *Brownie*, is shown in Fig. 65.1. Brownie was a battery-powered vacuum cleaner with a diameter of 40 cm, and at 18 kg, a super heavy weight compared to today’s domestic cleaning robots. It was equipped with a gyroscope, a ring of sonar sensors, and a dust sensor. Likely, it was limitations in battery technology for driving such a heavy robot, as well as the total cost, which prevented Brownie from become anything more than a prototype.

Six more years went by before Minolta presented its *Minolta Cleaning Robot* and the first European player, Electrolux, its Robot Vacuum Cleaner, later called Trilobite, which was presented to the public in BBC’s TV show *Tomorrows World* in 1996.

The devices had already become significantly smaller and lighter in these six years. The Minolta robot had dimensions of 321 mm × 320 mm × 170 mm and weighted about 8 kg. It was powered by nickel metal hybrid battery and used sonar and tactile sensors for obstacle detection, a cliff-sensor to discover staircases, and a gyroscope to track its position and orientation. Electrolux’ robot also had a sophisticated sonar system, which let it follow contours and even return to a homing position. It already had the size and shape of later floor cleaning robots.

Five more domestic cleaning robots made their first appearance during this time, which we call the infancy of domestic cleaning robotics. Two of them only reached the proof of concept level: *AutoCleaner* from InMach Intelligent Machines – the German startup later developed low-cost navigation systems for the professional cleaning robot Robo40, which became commercially available in 2007 – and Koala from EPFL-Lami. AutoCleaner was the first domestic wet-cleaner proof of concept, which cleaned the floor using a rotating microfiber towel that was pulled through a water tank. Koala used a suction spout to reach corners. Two more robots reached at least the status of industrial prototypes, but were never commercialized: Dyson’s *DC06* and *Cye* from *Probotics*. DC06 was a unique domestic

Fig. 65.1 First generation of domestic floor cleaning robots (1985–1999)

Fig. 65.2 Second generation of domestic floor cleaning robots (2000–2008)

cleaning robot. It differed not only in terms of the announced list price of approximately US\$ 4000, but also in many other aspects: Dyson claimed that it had three onboard CPUs, more than 50 sensors for obstacle avoidance, cliff-detection, localization and more. On top of that came the unique Dual Cyclone cleaning technology. The DC06 never made it to the market. Neither did Cye. Cye was a small mobile robot that could pull and push a (semi-)regular vacuum cleaner. It was announced as the *first personal robot* which could not only vacuum the floor but also serve coffee or deliver mail. It is unclear if Cye ever delivered coffee or mail or vacuumed a real living room. It disappeared as quickly as it appeared. The last out of the nine first robots that we call first generation was the Kärcher RoboCleaner. Its successor RC3000 was amongst the first cleaning robots that had a docking station at which the robot could not only recharge its battery but also unload the dust, which it had collected. We will come back to the Kärcher RC3000 in the next section.

The first generation domestic floor cleaning robots shown in Fig. 65.1 were the ones presented to the public. However, they were by far not the only ones that were developed in the period between 1985 and 1999. By browsing over the patents in the field of cleaning robots during that period it becomes obvious that many of the big appliance and electronic device manufacturers worldwide performed research and development on domestic cleaning robots. Besides the ones mentioned above, one can find such big names as Nintendo, Mat-

sushita, Sanyo, Samsung, Honda, Procter & Gamble, Electrolux, Philips, Henkel and more. So, although only a few players dared to go public, domestic cleaning was already on the radar of many international enterprises. What kept them away from taking the next steps is not hard to guess. It was the risk of getting into a rather conservative and tight market – the cleaning business is extremely conservative – with a semimature technology carrying a price tag that looked quite differently than the one on well-established technology, such as traditional vacuum cleaners.

The Second Generation of Domestic Cleaning Robotics (2000–2008)

Figure 65.2 shows the second generation of domestic cleaning robots. What made the difference between the first and the second generation? The amount of experimentation regarding the overall design decreased, with the majority of manufacturers settling on the disc shape. The number of sensors decreased, as well as their level of sophistication. Sophisticated and expensive sensors such as sonar largely disappeared. Most designs were limited to very few, simple, and inexpensive sensors such as bumpers, simple one-dimensional range sensors, typically based on infrared (IR), and cliff sensors. This was most likely a rather painful lesson learned from the designs in the first generation. What roboticists considered the state of the art in mobile robotics: environmental sensing, map building, range sensors with high quality angular and range res-

olution, and combined localization and mapping, were far too expensive to be built into a domestic cleaning robot. Those robots had to compete with regular vacuum cleaners in a price range of a few hundred dollars. This competition imposed very harsh cost limits for the robotic components that could be built into a domestic cleaning robot: 50 to 100 USD and often less. These cost constraints had a significant impact on a very fundamental expectation of what cleaning robots should achieve: systematic coverage of the area to be cleaned. Cleaning was understood to be synonymous with covering an area with a systematic and intuitive motion while applying some type of cleaning operation. Most of the patents filed for the first generation of domestic cleaning robots mentioned above described cleaning robots that were supposed to cover their workspace in a systematic fashion.

Systematic coverage, however, is impossible without absolute positioning and without decent knowledge of the environment. The second generation of domestic cleaning robots had to provide a solution for this dilemma of systematic coverage with cheap and simple sensors, which must not cost more than several tens of dollars.

The solution to this dilemma was already proposed in some early prototypes. The idea was to waive the requirement of systematic coverage, which would also involve intuitive motion patterns, and instead produce *semisystematic* coverage and *semi-intuitive* motion patterns. This semisystematic coverage was achieved by a combination of random motion, hard-coded motion patterns such as spiral- or meander-shaped motions, which – considered alone – reflects some systematic coverage, and some other systematic and intuitive motion patterns, for example, following contours of walls or other objects in the workspace. The theory of stochastic process states that the mean squared distance of a particle that performs a random walk with respect to the origin of its motion increases proportionally with time. That implies that the particle moving in confined space will cover that space in a finite amount of time.

First-generation domestic cleaning robots like the Electrolux Robotics Vacuum Cleaner (later Trilobite) or the Kärcher Robot Cleaner (later Kärcher RC 3000) already used random motion combined with hard-coded motion patterns to achieve a certain degree of coverage. But apparently the insight that the attribute *robotic* in front of *vacuum cleaner* was not enough of a sales argument to justify a price three to five times higher than that of a regular vacuum cleaner was not so easy to digest. Some of the second-generation cleaning robots were offered for a price on the order of 1500 USD or even more. In the end these robots shared the same fate: they become shelf warmers.

This is also due to the fact that in 2002 a robot was launched which was to herald a breakthrough in domestic cleaning robotics: Roomba. Its creator, iRobot Inc., had learned the lesson that others were still struggling with: if you want to sell a domestic appliance, better sell it for a price that is known for domestic appliances. For the sake of fairness one has to mention that the traditional vacuum cleaner manufacturers had to design the robots so they matched the quality and performance level that could be expected from the brand name. They could not take the risk of making their product too poor. Therefore it easily became over specified compared to what the market required at the time. New manufacturers such as iRobot in contrast had no brand name to defend [65.1].

If it is a totally new device, which may not only cause excitement but also concerns and reservations, sell it for less and not for more. When Roomba entered the market it was sold for 199 USD. That was a price, which did not cause customers to think about whether they really needed it, whether the quality was good enough, or whether the device would get into every corner of a room or underneath every couch or bed. The creators of Roomba were also smart enough not to call it a robot. This that prevented many customers from developing wrong expectation of what robots could or should do.

The robot technology that was built into the Roomba was everything but new or revolutionary. Roomba used a suspended front-shield for contact-sensing, a low-cost infrared range-sensor for contour-following, a cliff-sensor to prevent it from falling down stair-cases, and it could detect photoelectric barriers, so-called *virtual walls*, which kept it from leaving a room or a certain part of its workspace. Roomba further used the combination of random motion and hardcoded area-covering motion patterns to achieve a certain level of coverage. All this technology was known before Roomba.

Still Roomba can be seen as a milestone not only in domestic robotics but also in robotics at large. Why is that? It was the first time in robotics history that robotics was no longer synonymous with high-tech, high-price. Roomba showed that automation of everyday service tasks, such as domestic cleaning, could be achieved with a moderate effort in terms of hardware and at a decent price, given that one accepts some graceful degradation in the overall performance. There is no such thing as a free lunch, not even in robotics and this degradation in the performance is the price to be paid. What turned Roomba into a milestone was the cost-effective design, where the limitations of low-cost hardware – in Roomba's case the sensors – were balanced out by smart heuristics for problem-solving. This

Table 65.1 Technical specification of a selection of second-generation domestic cleaning robots

					
Manufacturer	iRobot	Sharper Image	Electrolux	Kärcher	Yujin
Model	Roomba	eVac	Trilobite 2.0	RC 3000	iclebo

Price range	250 USD	100 USD	1300 EUR	1350 EUR	530 USD

design of a commercially viable product, at a price point competitive with nonrobotized solutions, turned Roomba into the first successful domestic cleaning robot, and the most frequently sold robot in the past 50 years.

In Table 65.1 we give an overview of the technical specifications of some of these second generation robots. A more complete overview is included in 065-bib43

The idea to develop and commercialize a domestic cleaning robot at a price level of 199 USD, comparable to the price of traditional domestic appliances, was very appealing to consumers. However, it was not an overly profitable business model, even if Roomba was manufactured in a low-wage country at a cost of significantly less than 100 USD. Extreme cost pressure, however, often compromises the quality of a product. So a decision to adhere to this low price of below 200 USD may also have been a decision against the quality of the prod-

uct. Today nearly a dozen models of Roomba are on the market, which differ mostly in terms of their cleaning technology and extra features. Their prices are in a range from 250 to 900 USD.

The Third Generation of Domestic Cleaning Robotics (2009–2012)

The second generation of domestic cleaning robots also provided their developers and distributors with a number of painful and partly contradictory insights:

- A domestic cleaning robot sold at a price that is significantly beyond the price of comparable non-robotic devices, runs a high risk of failing, because many customers may not be willing to pay extra money for a cleaning robot just because it is a robot.
- A domestic cleaning robot sold at the same price level as an inexpensive comparable appliance, runs a high risk of failing, because the low price may

compromise the quality and functionality of the product, and many customers may not be willing to pay even a rather low price for a product that is known to be of poor quality.

- For most customers – traditional, as well as technophiles – efficient cleaning requires systematic and efficient coverage of the workspace. A domestic cleaning robot that uses sophisticated sensors to achieve systematic and efficient coverage may easily end up with a price tag that is significantly above the price of a comparable nonrobotic device and hence runs a high risk of failure.
- A domestic cleaning robot, which refrains from using expensive sensors to achieve systematic coverage but instead uses low-cost sensors for collision avoidance, fall protection, and confinement as well as using random motion combined with some hard-coded motion patterns to achieve a certain level of coverage, runs a risk of not satisfying those customers who expect systematic cleaning and coverage.

From a developers point of view these lessons sound as if customers expect not less than to square the circle. The truth is that customers do not care about squares and circles. They expect value for money.

With the insights above one could classify potential customers of domestic cleaning robots into three categories:

- Customers who only care about the price and not so much about quality and functionality. The criterion for this class of customers was obvious: reduce the price as much as possible without ignoring that there may be a bottom line for what customers might expect in terms of quality and functionality.
- Customers who care about the price and quality, but are willing to adjust their expectations of functionality and efficiency. The criterion for such customers was to reduce the price but only to a certain extent, which does not compromise the quality of the product too much. Expectations of such customers in terms of efficiency (i.e., systematic coverage) can be compensated by auxiliary equipment such as automatic charging stations.
- Customers, who care about price, quality, and efficiency. Apparently these customers are the most demanding. None of the second-generation domestic cleaning robots has really managed to satisfy them. The criterion to serve them would be to develop a low-cost navigation system based on low-cost sensors that provides systematic coverage.

As satisfying the last group of customers, which is also likely the largest of the three groups, seemed

nearly impossible, the third generation of domestic cleaning robots have diverged somewhat. Some manufacturers have focused on products that serve the first category of customers, some serve the second group and some even made an effort to square the circle.

May they be successful in the end or not, what cannot be overlooked is the explosion of the number of manufacturers and distributors of domestic cleaning robots in the past five years. At the end of the 2012, twenty-seven years after the first mention of a domestic cleaning robot to the public, Amazon alone listed more than 131 results under the key word *robot vacuum cleaner*, with 14 manufacturers and suppliers. The business to business (B2B) portal www.made-in-china.com lists more than 71 companies for *robot vacuum cleaner* and a total of 875 products. Some of these 875 robot vacuum cleaners look surprisingly similar to the products sold over B2C platforms under very-well known brand names.

In Fig. 65.3 we show some of the products, which primarily intend to serve customers of the first category and therefore stayed under a price of 200 EUR. Figure 65.3a shows a model series of six cleaning robots made by XRobot of the Chinese manufacturer Shenzhen Silver Star Intelligent Electronics Ltd. In B2B trading these robots cost between 64 and 102 USD per piece at a minimum order of 500 pieces. Most models of this series are also sold under the brand name of European and American enterprises. Figure 65.3b shows another series of still rather cheap robotic vacuum cleaners. The attentive reader may notice that the robots in the left and the right figure are not totally unique. Some just have different names and different prices. This is not entirely unintended. It just illustrates that in domestic cleaning robotics the value creation chain is no longer limited to the developers and manufacturers, just as in every other business.

Apart from a few minor details, all robots in Fig. 65.3 use very similar, though not to say the same, technology. They use very few and very cheap (contact, cliff, sometimes dirt) sensors and random motion combined with preprogrammed motion patterns. The vacuum technology consists of a rotating brush, sometimes combined with a small fan. Not surprisingly, robotic vacuum cleaners like the ones in Fig. 65.3 are often called Roomba-clones. The collection of robots in Fig. 65.3 is neither representative nor comprehensive.

Roomba has undoubtedly written robot history. It is the merit of Roomba and its developers that domestic cleaning robots are no longer considered as gadgets but as real appliances. Roomba has opened the door for all

Fig. 65.3 Third generation of domestic floor cleaning robots: low-cost, low-tech

Fig. 65.4 The seventh generation of Roombas

the cleaning robots mentioned above, be they Roomba-clones or not. And Roomba is the by far the best-selling robot ever.

In Fig. 65.4 we show some of the grandchildren and great-grandchildren of the very first Roomba, which started in 2002. The Roomba has gone through several facelifts in these ten years. The latest series, the Roomba 700 is the sixth generation of Roombas. It has matured quite a bit in many respects. It has matured in terms of handling, cleaning technology, obstacle avoidance and navigation technology. At the same time Roomba is delivered in more than a dozen versions, ranging from 250 to 900 USD. These versions differ in the design, in the sophistication of the user interface, in the navigation and coverage strategies, and in the details of the cleaning technology.

According to iRobot more than 6 million units have been sold in the ten years of its existence. Roomba has certainly satisfied quite a number of customers. It is built with good quality, and comes with a self-charging

home base and other auxiliary equipment. What has not changed, however, is the basic strategy for covering the workspace. The sixth generation just like the first uses random motion with some precoded motion patterns and heuristics.

This raises one rather fundamental question. Will Roomba's success story continue? Will it maintain its market position? Or has Roomba possibly reached or even passed its summit? These questions will not be answered before the third edition of this book, as any statement in this direction would be pure speculation.

In any case, there are a few recent domestic cleaning robots, which demonstrate that covering a work space in a systematic fashion does not necessarily require expensive sensing, that would push the price for a domestic cleaning robot to a level which customers would not be willing to pay.

Four different key technologies enable the devices shown in Table 65.2 to localize themselves and navigate

Table 65.2 Systematic cleaning at low-cost. The information in this table was partly collected from the websites and the technical documentation of the manufactures and partly from public websites such as www.botroom.com, staubsaugerroboter-test.org, www.robotreviews.com, www.geek.com, gizmodo.com, www.engadget.com

in an unknown domestic workspace and systematically cover that space:

- Visual odometry, with a camera pointing to the ceiling, combined with simultaneous localization and mapping (SLAM) used by LG Homebot, Samsung Navibot SR 8xxx, iclebo smart and Philips Home-run,
- Localization, using infra read patterns projected to the ceiling, and mapping based on contact information used by Mint,
- Proprioceptive motion estimation, using inexpensive inertial measurement units (including inexpensive gyroscopes and accelerometers)
- Simultaneous localization and mapping (SLAM), using, for example a one-dimensional laser rangefinder like Neato XV-xx.

These technologies by themselves are not entirely new. As a matter of fact methods such as simultaneous localization and mapping, visual odometry, and virtual landmark based navigation are not state of the technologies form a scientific point of view.

The true achievement of the developers of the above systems, which cannot be assessed high enough, is that they managed to reduce the cost of these technologies and at the same time make them robust enough for 24/7 operation. These key technologies will be described in

more detail in Sect. 65.1.2 Enabling Technologies. A review of domestic vacuum cleaning robots and some criteria to evaluate their performance are presented in [VIDEO 727](#) and [VIDEO 729](#).

65.1.2 Domestic Window Cleaning

Window cleaning does not seem to be significantly more pleasant housework as floor cleaning. Notwithstanding, robotic window cleaners have not experienced similar attention or progress as floor cleaners. As a matter of fact, today there are only three commercial robotic window cleaners on the market, shown in Fig. 65.5. www.made-in-china.com does not even list one entry for *window cleaning robot*, although two of the three commercial products are Chinese brands. Why is that so, given the fact that domestic floor cleaning has become a billion-dollar business? The answer to this question has two parts: an economic and a technical one.

The economic one is that windows in private homes are cleaned far less often than floors. Customers may hesitate to buy expensive equipment for a task that needs to be done once a month or even less. So the market for domestic window cleaners is presumably much smaller than that for floor cleaners.

The technical one refers to the technical hurdles that have to be overcome. The technical problems that robotic window cleaners have to face are:

- Adhesion to a vertical, fragile surface, which possibly needs to be moistened in order to be cleaned, and related, the power supply necessary to produce that adhesion.
- Requirements for cleaning performance; people may tolerate if the floor is not 100% clean, but nobody would buy a window cleaner that leaves streaks on the window.

While floor cleaners do not bother about gravity and falling down unless they are near staircases or ledges, gravity is an essential problem for window-cleaning robots, and the solutions are usually not very cheap. Special mechanisms have to be designed for secure motion. Typically special tether mechanisms prevent the robots from falling. Special locomotion mechanisms have to create enough adhesion force to hold a robot attached to a flat, vertical, damageable surface such as glass and at the same time move the body up and down and sideways. These mechanisms have to be small and light and create enough adhesion forces as well as low energy and resource consumption.

The two robotic window cleaners shown in Fig. 65.6, RACOON and QUIRL, are research prototypes, which were developed by Fraunhofer Institute for

Manufacturing Engineering and Automation (IPA) in Germany. In these prototypes the adhesion problem was solved by means of suction cups. RACOON used caterpillar drives that were equipped with passive suction cups. Passive means that the system does not actively create a vacuum in the cup. Rather a small valve aerates or seals the suction cup depending on the position of the cup along the drive. Drives with passive suction cups have the advantage of moderate energy consumption. They have, however, one severe disadvantage. They tend to lose their adhesion after a while. The reason for this is the torque that acts on the center of gravity of the system. Due to this torque there is a traction force acting on the upper cups while at the same time pressure is exerted on the lower cups. Without any attractive force acting on the upper cups the adhesion there gets weaker and eventually the system falls. Therefore passive suction cups are rarely practical.

An apparent solution to this problem is the use of active suction pumps, which generate a vacuum under the upper suction cups. This solution prevents the system from falling. However, supplying the vacuum to the cups makes the system significantly more complex, heavier, and larger. Researchers at Fraunhofer IPA [65.2] have therefore invented a smart solution, which gets by with passive cups, but gets around the problem of decreasing adhesion. The solution uses a spacer at the rear of the vehicle. This spacer neutralizes the torque around the center of gravity which is typical for a systems with passive suction cups. The spacer causes a traction force which acts on the lower suction cups. This traction force creates a torque around the spacer, which counteracts the torque around the center of gravity and also causes a pressure on the upper suction cups. RACOON was presented at the Hannover Fair in 2002 and got quite some attention. But it never became a product. Neither became its successor QUIRL.

In QUIRL, the number of components, the weight, and the size of the system were significantly optimized. The main functions *cleaning*, *holding*, and *moving* were unified in one single component. QUIRL consisted of

Fig. 65.6 (a) RACOON and (b) QUIRL, two early research prototypes of domestic window cleaning robots

Fig.65.5a–c Commercial robotics window cleaners (a) Windoro, (b) Winbot, (c) Hobot

two vacuum cups that were attached to a common frame which were driven by two separate motors, which rotated independently of each other. The overall motion of QUIRL could be controlled by selecting the velocities and rotational directions of the vacuum cups. If the motor of one vacuum cup was turned off and the cup did not rotate, QUIRL rotated around this fixed cup. If both motors and cups rotated in the same direction this led to an overall rotation of QUIRL about its vertical axis. If both drives rotated in the opposite direction at exactly the same velocity then QUIRL made a linear motion. If both drives rotated in the opposite direction but their velocities were not identical then the translational motion was superimposed by a rotational motion and QUIRL moved along a curved trajectory. In order to clean the surface some cleaning mechanism or tool needed to be fixed to the vacuum cups. By attaching, for example, specific cleaning towels in the cups the abrasion effect was increased and a very good cleaning performance could be achieved.

The field of robotic window cleaning has not made as much progress as domestic floor cleaning, but it has still made progress. In Fig. 65.5 we show three commercially available window cleaners – Windoro WCR I001, Winbot 7, and Hobot 168 – available today.

In 2010 the South-Korean enterprise Ilshim Global Co. Ltd. introduced its commercial window cleaner Windoro (WCR). Windoro consists of two modules, a navigator module and a cleaning module that are held together by two strong neodymium permanent magnets, whose distance can be adjusted. The navigator module and the cleaning module are placed on the inner and outer side of the window, respectively, like a sandwich with the glass pane in between. The two modules operate as a tandem. The navigator module has a differential drive system with two wide-based rubber wheels. Also the cleaning unit moves on two rubber wheels, which serve as spacers for the four spinning cleaning pads. When the navigator module moves, the cleaning module on the other side of the window moves with it. The linkage by permanent magnets obviously has one rather fundamental advantage. As long as the window does not exceed a certain thickness, namely 28 mm, the permanent magnets hold the robot safely attached

to the window. Windoro cannot fall, even if its battery runs out of power. For that reason Windoro does not need any safety mechanism like a safety rope. Unfortunately there is a price to pay for this: it is very difficult and unhandy if not impossible to use Windoro if you cannot open the window that you want to clean.

Windoro first explores the width and height of the window before it then starts to clean the window from the top to the bottom in a zig-zag motion, with a velocity of 8 cm/s. While the robot moves over the window the cleaning module sprays a cleaning solution onto the window surface. With four spinning microfiber pads the cleaning module removes dirt and sprayed solution from the surface.

The second commercial window-cleaning robot is Winbot, a product of the Chinese company Ecovacs, which has established its own brand. Winbot was first introduced in 2011. The most recent version Winbot 7 was presented at the electronics fair CES (Consumer Electronics Show) 2013 in Las Vegas. Ecovacs also manufactures and distributes the robotic vacuum cleaner family Deebot.

Winbot uses two suction rings and a vacuum pump for the adhesion at the window. The outer ring also serves as a safety mechanism. If the air pressure in the ring increases, that means Winbot has reached the edge of a window plane, it backs up, turns around and moves in a different direction. A second suction cup serves as a safety anchor for Winbot while it moves. It is connected to Winbot by a safety rope and catches the robot if it falls. Winbot can move at a velocity of approximately 15 cm/s. Its drive system consists of two differentially driven anti-slip rubber tracks.

After it has been turned on, Winbot, like Windoro, first explores the height and width of the window, then calculates a zig-zag path that covers the window area and finally executes this path. Winbot has no active cleaning technology such as spinning pads. It uses two micro-fiber towels that are attached to two plates at the front and at the rear of the robot. The micro-fiber towel in the front has to be moistened before Winbot starts moving. It resolves and removes the dirt. A rubber blade behind the front towel removes the remaining moisture.

Fig. 65.7 Robotics pool cleaners

The micro-fiber towel in the rear of the robot finally dries the window.

The third, and most recent, system, Hobot 168, is a product of the Taiwanese company Hobot Technology Inc. It was first presented at IFA 2012 (Internationale Funk Ausstellung) in Berlin and launched in summer 2013. It looks surprisingly similar to Quirl in Fig. 65.5 and apparently uses a similar adhesion and locomotion mechanism, namely two rotating vacuum cubs, to move across the window.

The preceding paragraphs read as if the times are over where windows had to be cleaned by hand. Regrettably this is not the case. Although all three devices reasonably solved the adhesion problem their overall performance is modest. Several tests by housewives and magazines came to the same sobering conclusion: There is a lot of noise and very little cleaning. As a matter of fact, although the navigation problem on a vertical rectangular surface, which is free of obstacles apart from the window frame, seems to be a solvable one, Hobot 168 and Winbot showed a rather poor performance in terms of systematic coverage. After a semisuccessful effort to explore the width and height of the window, Winbot, in one of the tests, moved more or less erratically for several minutes, before it gave up somewhere along the road. Several of the currently available commercial window cleaning robots are reviewed in [VIDEO 734](#), [VIDEO 735](#), [VIDEO 736](#), and [VIDEO 737](#).

65.1.3 Pool Cleaning

While robotic floor cleaner and window cleaner were still struggling to get rid of the image of only being the crazy ideas of engineers and researchers at the be-

ginning of the millennium, pool-cleaning robots were already well-established products. This may be due to the fact that the challenge of cleaning a rectangular pool is rather modest and so is the *robotic technology* used in robotic pool cleaners. It may also be due to the fact that pool owners belong to a class of customers who did not create the same price pressure as the ordinary housewife.

First patents on self-propelled pool cleaning devices date back to 1965, three years after the first industrial robot was installed. Ferdinand Chauvier, a South African engineer, could possibly be considered the father of automated pool cleaning. He developed several generations of devices for pool cleaning before he finally marketed *Kreepy Krauly*, the first automated pool cleaner in 1974. Kreepy Krauly was not only the first one of its kind but also the very first domestic service robot ever, 15 years before Joe Engelberg published his book *Robots in Service* at MIT Press in 1989 and coined the term *service robot*. Since then the technology of pool cleaning robots hasn't changed much.

As one can see in Fig. 65.7, most pool cleaners have track drives, which are operated differentially. Typically the motors that drive the tracks are also connected to the front and rear scrubbing brushes, which clean the pool surface, while the robot moves. While tracked drive system were rather common for the early generations of pool cleaners, newer pool cleaners also use wheel drives, for example, the Polaris 9400 from Zodiac Pool Systems. A wheel drive can be advantageous because the space between the bottom of the robot and the ground allows a better water flow and a higher throughput. Also Zodiac claims that Polaris 9400 has higher maneuverability.

Fig. 65.8 Example of the navigation and cleaning strategy of a robotic pool cleaner

Since most sensors, which are used in mobile robots or in aerial robots do not work under water, the sensor modalities that are used by pool cleaners are manageable. Unfortunately the manufacturers do not disclose much about the sensor technology and technology in general used in their system. So we need to speculate a bit about how the behaviors shown in the commercials are internally implemented.

Most pool cleaners claim to be capable of avoiding obstacles. When they sense a collision, they back up for a certain distance, reverse the direction of motion and then continue, possibly on a track parallel to the one that led to the obstacle. They can *recognize* the walls of a pool, which form the borders of their workspace. They can even climb up the walls of a pool, float along the perimeter and then submerge again. They can *explore* the length and width of a pool. They can drive a certain distance before they change direction.

All these behaviors require a combination of several of the following sensors: *odometry* to measure traveled distance, an *inclinometer* to sense if the robot starts moving upward, e.g., when it keeps pushing against a wall and the front wheels start moving in a vertical direction, *contact sensors* to detect when the robot collides with an obstacle – be it a wall of the pool or a real obstacle on the ground of the pool – *sensor to measure the motor current*, which can be used in addition or instead of a collision sensor to detect if the robot pushes against an object, and possibly an *inertial measurement unit* to correct the heading when driving. Polaris and possibly other systems as well use an accelerometer to constantly determine its position in the pool. A sensor modality, which might be used underwater for obstacle detection and avoidance is laser, with wavelengths in the lower nano-meter range (e.g., 405 nm blue laser). But it is unknown if this principle has been considered for pool-cleaners.

In terms of *navigation and coverage* pool cleaners follow similar strategies to those floor cleaners, which we roughly classified as Roomba-clones. Earlier pool

cleaners used random motion pattern. The newer ones shown in Fig. 65.7 use certain heuristics and strategies to perform some form of localization and exploration of the pool. The Maytronics Dolphin, for example, first explores the length and the width of a pool. After being dropped into the pool and floating to the bottom of the floor it crosses the pool until it hits the first wall. With the support of a thruster it climbs up the wall until it reaches the surface. There it hovers to the side before it submerges again and moves back to the ground of the pool. Next it moves to the opposite side of the pool, climbs up the wall, hovers to the side and glides back to the ground. While moving on the ground from one wall to the other Dolphin measures the distance from wall to wall. Once it glides back from the second wall it moves halfway back toward the other wall. It then makes a 90° turn and repeats the exploration for the second set of opposite walls. After the exploration is completed, Dolphin knows the length and width of the pool and plans a pattern of parallel and orthogonal tracks as shown in Fig. 65.8 that in the end covers the entire pool.

Removing dirt and debris from the ground and the walls of a pool, requires loosening the dirt – if it is not loose already – and to soak it into a container, otherwise the dirt would only be circulated in the pool. The container is typically a jet pipe with a filter at one end that holds the dirt back while the water flows through the pipe back into the pool. Soaking in water and debris from the floor into a filter and pumping it back into the pool requires significant suction power. This is the reason why pool cleaners typically have an external power supply. This motor serves as a pump and as a thruster at the same time. Both effects together allow pool cleaners to easily climb up vertical walls. Using inflation at the bottom of the robot, and a water jet ejected at the top, enough traction power is created that both tracked and wheeled pool cleaners can drive up vertical surfaces.

As mentioned earlier, the cleaning technology, besides the water pump and the filter to keep back the debris, consists of a system of counter-rotating rubber brushes which brush the debris underneath the pool cleaner, where it ends up in the intake socket of the water pump. [VIDEO 739](#) and [VIDEO 740](#) compare a selection of home pool cleaning robots.

65.1.4 Lawn Mowing

Together with robotic pool cleaners and domestic floor cleaners, robotic lawnmowers today count as regular everyday products. People no longer consider them mystical pieces of technology, which have their own life and which at times become so autonomous that the user no longer knows what they are after.

Fig. 65.9 Example for virtual fence and coverage strategy (random motion) of robotics lawnmowers

It is not surprising that robotic lawnmowers have a lot in common with domestic floor cleaners. They have to cover a workspace of a certain size with as little interaction with the owner as possible. They have to perform a certain operation to the surface such as cleaning the floor or mowing the lawn. They must not collide with any obstacles and if they do, they should at least not cause any damage. They must not get stuck anywhere in the environment and they should not leave the workspace without authorization.

The challenge for lawnmowers, much the same for domestic floor cleaners, is the systematic coverage of the workspace, which in turn requires precise positioning and mapping of the workspace. Given the fact that the price pressure is not as back-breaking as for robotic floor cleaners – there are not that many robotic lawnmowers which costs less than 1000 EUR – why not invest a little more in sensing and especially in position sensing and obtain a decent solution for the localization and coverage problem?

The answer to this question is: things are not that simple. Lawnmowers operate outdoors and none of the solution developed for the floor-cleaners in Fig. 65.2 will work. Regular **GPS** (global positioning system) has an accuracy of several meters and has a tendency to deliver erratic readings, which would lead to equally erratic motions of the lawnmowers. As a matter of fact Automower 220 from Husquana uses **GPS**, but only as an antitheft protection device. Differential **GPS**, which would provide accuracy below one meter, would be too expensive for an affordable robotics lawnmower. In a nutshell, absolute positioning or **SLAM**, which would be necessary to cover a large outdoor area like a garden in a systematic fashion, is not practical.

In order to cover their workspace robotics lawnmowers use similar strategies to the Roomba-like floor cleaners. They refer to heuristics, which do not provide an optimal performance but still show a decent result. Using sensors such as gyroscopes, digital compasses, or inertial measurement units, robotic lawnmowers follow a certain heading and cover the workspace as much as possible by parallel tracks. They move along a straight line until they hit an obstacle or reach the border of the workspace. There they back up to become clear

from the obstacle, make a U-turn by 180° and drive back the way they came. Another heuristic that is frequently applied by robotic lawnmowers is the random motion shown also in Fig. 65.9. The mower moves along a straight line until it hits an obstacle or reaches the border of the workspace but then it does not just reverse but chooses a new direction randomly.

Since robotic lawnmowers move in open space, there is a danger that they leave their workspace and travel to areas where they are not supposed to be. For floor cleaners so-called virtual walls or fences solve this problem. Virtual walls are realized by infra read light beams emitted by some projectors, which can be placed in the workspace. The robots can sense these infrared light beams and consider them as obstacles, which evoke the typical obstacle avoidance behaviors. Lawnmowers use a similar technique, which is based on induction rather than light. To mark the border of the robot's workspace the owner has to place a wire around the area, which the robot must not leave (Fig. 65.9). This wire is connected to a low-voltage alternating current source. When the robot approaches the wire an inductivity sensor senses the current in the wire and causes the robot to reverse. Today most lawn mowers use a more sophisticated so-called *true in/out systems*, where the position is permanently tracked, not only when the robot approaches or passes the virtual fence [65.3].

The very first robotic lawnmowers had to be recharged manually. To avoid an all too frequent involvement of the human into the operation, Husquarna – one of the pioneers in robotic lawn mowing – equipped its first mower with solar panels and called it *SolarMower*. SolarMower was released in 1995, and was one of the first robotics lawnmowers. Nowadays, all lawnmowers come with a base station where they can recharge their batteries without human intervention. Also solar panels are coming back as power source, however only as auxiliary power to increase the performance and runtime between two charges and not as main power supply.

Given the fact, that robotic lawnmowers do have poor positioning capabilities, it is somewhat tricky to guide them back to the docking station once the battery

Fig. 65.10 Robotic lawnmower

gets low and needs to be recharged. Some of the lawnmowers shown in Fig. 65.10 use special wires which radiate from the position of the docking station. This way a robot only needs to follow such a radiating wire to return to the docking station on the fastest way. Another strategy is to follow the wire at the workspace border. That will eventually lead the robot back to the docking station.

An exception is the Bosch Indego, which is equipped with mapping and localization capabilities. This allows Indego to plan a path that leads to a point close to the docking station. Then the robot can follow a wire for the docking maneuver [65.1].

To comply with the safety regulations and to avoid any injuries of humans or animals the cutting mechanism has to be very lightweight and designed such that it is guaranteed to stop if the device tilts or is lifted. The cutting mechanism of robotic lawnmowers typically consists of a rotating disc with three razor-like blades, which automatically retract into their mountings if the robot is stopped unscheduled, for example, if it hits an obstacle or is lifted.

Naturally the lightweight design limits the thickness of the grass that can be cut. Also it is important for the proper functioning of robotic lawnmowers that the lawn, which is to be cut, is not too high. This in turn requires a rather regular if not continuous operation of the lawnmowers. With regular use of the lawnmowers the grass cuttings are short enough to quickly decompose into nutritious compost, so there is no need to remove the cuttings after the lawn is mowed.

Figure 65.10 shows some of the better-known robotic lawnmowers on the market today. Besides the pioneers in robotic lawn mowing Husqvarna, Friendly Robotics and Zucchetti also a number of new players have entered the market, most noticeably the German automotive supplier Bosch and the Japanese car manufacturer Honda, which has set a milestone in non-industrial robotics with its humanoid robot Asimo.

We certainly do not claim that the collection in Fig. 65.10 is complete. Like for domestic floor cleaning, Chinese B2B portals such as www.made-in-china.com or www.alibaba.com list around a hundred products under the category of robotic lawnmowers and 35 suppliers; the market development for robotic lawnmowers in the past five years was not quite as overwhelming as for domestic floor cleaners but was still remarkable. In Table 65.3 we show the technical specifications of a selection of lawnmowers from Fig. 65.10.

65.1.5 Sports Robotics

A subdomain of domestic robotics that was not included in the first edition of this handbook, because it virtually did not exist, or it was not visible at that time, is *sports robotics*. What is a sports robot? Since an official definition of this term does not yet exist – at least we haven't found one – we take the liberty and provide such a definition here. We define a sports robot as a *robotic device*, which either *supports* the human user in their physical exercises as a *coach* or a *companion*, or acts as an opponent in a game. An important aspect of this definition is the physical exercise of the human, which is supported or challenged.

We would like to emphasize that the above definition does not include any form of entertainment robots, which play games such as soccer against each other but do not involve any human activity other than watching.

In Fig. 65.11 we show three examples of *robotic baseball players*. As the name says the *Headless Batman* can act as a batter at least for exercising. It rather successfully hits baseballs thrown at it in many ways. The kinematic structure consists of *two arms, one leg and no head*, as its developer, an industrial designer from Robocross, likes to call it, and is made from auto parts, steel pipes, and pneumatic hoses. The pneumatic hoses are parts of its pneumatic actuation by an air

Fig. 65.11 Robotic baseball players

compressor. The *Headless Batsman* is fully controlled by a human operator via a remote control, which has

three buttons: one to control the robot's hip, a second one that actuates the arms and a third one to lift

Fig. 65.12 (a) JoggoBot and (b) RUFUS two robotic sports companions

and drop the inside shoulder, changing the trajectory of its swing. Similar mechanisms like *Headless Batsman* were developed at Hiroshima University and Tokyo University.

The counterpart of *Headless Batsman* is a pitching machine, which is operated with the same remote control. The barrel of the machine is sawn-off fire extinguisher whose other end is directly connected to a one-inch port poppet valve, which in turn is connected to an 8 bar air pressure tank. The air pressure tank is supplied from a screw compressor. The charging mechanism consists of a double rod actuator with a ring welded horizontally on to the end. Mounted above the ring is a magazine that holds up to 10 balls, which directly drop into the ring. For a pitch the actuator moves the ring with the ball over the edge of the barrel, where it falls on to a small guide. From there the balls rolls backward into the barrel. The actuated ring is covered by a steel strip, which holds back the other balls in the magazine until the actuated ring returns to its initial position. Since both mechanisms are remotely controlled, the human, who controls them, can actually sit in a chair next to the playground and let the robots play against each other. Such a use would clearly violate the above definition of a sports robot but does not seem to be the one that is primarily intended.

Another robot that can throw baseballs is Philliebot (VIDEO 748) developed in University of Pennsylvania's GRASP laboratory. Philliebot was developed in a couple of weeks using only spare parts in the GRASP lab. It uses a Segway as mobile base, a Barret arm, and pneumatically actuated wrist to create the necessary dynamics for the pitch. When the button is pressed the arm moves to the back of the robot and then accelerates its motion toward the target of its pitch. When the arm reaches the highest point of motion the pneumatic wrist cylinder delivers a burst of compressed carbon dioxide to snap the wrist forward and release the ball. What remains is the question of why use robotic equipment worth several tens of thousands of dollars to throw

a baseball, given that pitching machines have existed for many years. According to the developers, the fact that Philliebot is mobile and its software can be tweaked to vary pitch velocity and trajectory was enough to justify the experimentation.

The two sports robots shown in Fig. 65.12 do not really seduce their users to sit in a chair and relax. They both serve as so-called *robotic running coaches* or *running companions*.

Researchers at the Royal Melbourne Institute of Technology in Australia have redesigned a commercially available Parrot AR Drone quadcopter and turned it into an autonomous, flying running partner for joggers, called JoggoBot [65.4]. JoggoBot uses an integrated, front-mounted camera to detect and track a special patten printed on the T-shirt worn by the jogger. JoggoBot takes off when the camera registers the pattern and rises to about the same height as the pattern on the t-shirt. An internal sensor determines JoggoBot's altitude. JoggoBot can be set into a *companion mode*, in which it flies at a steady pace at a relative distance of about three meters to the jogger or in a *coach mode* in which it flies at a slightly more challenging speed.

There are two features of JoggoBot that make the device somewhat limited: first the capacity of the battery limits the flight time to 20 min, which in turns limits the time for exercise; for a short run, this is certainly ok, but for serious training this is insufficient. Second, JoggoBot can only fly in a straight line, to let JoggoBot follow an arbitrary path the jogger needs to remotely control JoggoBot's flight path.

A slightly different concept of a jogging companion is pursued in RUFUS (VIDEO 747), which is developed by runfun (www.runfun.com), a German startup company. RUFUS is an electrically driven, automatically guided, ground vehicle that supports and guides a runner during his/her training. RUFUS plays the role of a *personal running coach*. It fulfills a similar function to a treadmill, which exposes its user to a varying strain by varying its velocity and inclination and thereby improves the fitness, endurance, and resilience of the cardio-vascular system of the user. Unlike a treadmill, RUFUS is not a stationary device, however. It drives ahead of the runner like a pace maker in a marathon or a fake rabbit in a dog race, and sets the runner's speed. RUFUS's velocity is set either manually or automatically via a training program.

If operated in *manual mode* the velocity is either set directly as a velocity set point or indirectly as a heart-beat set point. If the training guidance is based on the heartbeat, then RUFUS controls its velocity such that the runner exercises optimally and continuously within a certain heartbeat interval under a moderate stain of the cardiovascular system.

Fig. 65.13 Tele-presence robots and robotic avatars

This has a twofold use: on the one hand this prevents users from overstressing themselves through overambitious and intensive training modules, possibly from even injuring him or herself. Such a protection function is beneficial for unfit or untrained runners. On the other hand RUFUS facilitates optimal training effect and progress through a careful guidance of the training.

The training effect can be further improved if RUFUS is operated in the *program mode* instead of the manual mode. In this mode RUFUS executes complete training modules, for example pyramid speed interval workouts, which are customized to the user. Such training modules are typically elaborated on by physiotherapists or sports physicians. They can be downloaded to the RUFUS embedded PC like an app from an app store.

RUFUS has a major advantage over JoggoBot. It has a battery capacity that allows it driving for about six hours on a flat road without recharging.

65.1.6 Tele-Presence

In a world in which not only large, but even small and medium-sized enterprises operate globally, in which families are scattered over continents, in which ubiquitous presence seems to become an essential requirement for professional progress, and in which professional services are more and more delivered over the internet,

tele-presence has become a fast growing market in the past years.

Robotics adds a very important aspect to plain *tele-vision* by turning it into *tele-presence*: embodiment and remotely controlled motion. As tele-presence is nothing but the combination of tele-vision and tele-operation using a robotic device, which are often called *tele-presence robots* or *robotic avatars*.

Tele-presence robots offer a whole spectrum of services and applications ranging from plain mobile video-conferencing systems to tele-surveillance, tele-diagnosing, and tele-care, to tele-teaching and tele-commuting. The term *tele-commuting* was coined by Scott Hassan, a Google developer of the early days, nowadays entrepreneur and investor, and founder of WillowGarage and Suitable Technologies, the manufacturer of Beam-RPD (see also Table 65.4).

A *tele-presence robot* typically consists of a mobile robotic platform that:

- Can be tele-operated through some user-interface,
- Carries a camera, which often can be actuated separately (via a pan-tilt unit) and allow the operator to actively explore the remote environment, and
- Carries a display, which allows those at the remote site to see the operator of the tele-presence system and communicate and interact with it.

Figure 65.13 shows a collection of such tele-presence robots. The devices range from a price of

Table 65.4 Technical specification of a selection of tele-presence robots

				
Manufacturer	Double Robotics	Vgo Communications	Gostai	Suitable Technologies
Model	Double	VGo	Jazz Connect	Beam RPD
Height	120–150 cm	120 cm	100.5 cm	5 feet, 2 inch
Weight	7 kg	9 kg	8 kg	45 kg
Screen size	9, 7'' (iPad)	6''	5''	17''
Camera/field of view			High resolution/ wide angle, up to 640 × 480 pixels at 25 fps	Two wide-angle HD cameras
Video conferencing	Open-tok	VGo video conf.	2-way audio and video for remote discussions	–
Network	WiFi	WiFi / 4G / LTE	WiFi	WiFi (two dual-band radios) / 4G
Remote Control	iPad App	VGo App	Intuitive control interface on internet browser	Beam software client, mouse, keyboard, or Xbox controller

Run time (h)	8	12	5	8
Docking station	–	Yes auto-docking	Yes auto-docking	Yes

some US\$ 1500 for TeleMe from MantaroBot to more than ten-fold that amount for Beam RPD from Suitable Technologies. The system **RP-VITA** (Remote Presence Virtual + Independent Telemedicine Assistant) emerging from a cooperation between InTouch Health and iRobot is available only for lease, at a monthly fee of \$ 4700. Giraff is the result of a European research project lead by Giraff Technologies funded by the European Commission and is not commercially available yet.

Not all tele-presence systems shown in Fig. 65.13 can be classified as domestic robots. A system that clearly stands out and is by no means a domestic robot is **RP-VITA** by InTouch Health and iRobot. **RP-VITA** is a remote healthcare system. **RP-VITA** shall enable doctors to command any clinical, patient or care team management process remotely. **RP-VITA** has a full-fledged autonomous navigation system that allows the personnel to focus on the patient care task rather than on remote navigation. This feature has been awarded clearance by the US Food and Drug Association (FDA).

RP-VITA further provides access to important clinical data to support physicians, nurses and other care personnel in their diagnosis and other medical workflow. For example **RP-VITA** connects with diagnostic devices such as ultrasound and comes equipped with the latest electronic stethoscope. So **RP-VITA** is in a class of its own, which may also justify the higher price.

Apart from **RP-VITA**, the tele-presence robots shown in Fig. 65.13, can all be classified as semiprofessional or domestic service robots. The functionalities and services they offer do not necessarily vary on the same scale as their prices. This can be seen by a comparison of two of the above systems: Double and Beam RPD (see also Table 65.4).

Double is not much more than a mobile iPad equipped with the video-conferencing system Opentok. The mobile base uses a Segway-like dual-wheeled drive system that can balance a pole, which holds the iPad. When Double stands still, two retractable kickstands are deployed and allow the system to put the control system in an idle mode and save energy. Double can

be remotely controlled and driven around a remote site through an app installed on a second iPad that enables communication with all known Doubles over the web. The height of the iPad holder can be remotely adjusted to enable communication at eye-level. Double Robotics list a number of potential services and applications for which Double could be used: Companies with sites at various locations can use Double to improve communication and collaboration between remote teams. Families can use Double to communicate with family members living abroad. Museums and art galleries can use Doubles to offer remote tours through their exhibitions.

Beam RPD uses two HD cameras with custom wide-angle lenses instead of the plain iPad camera. This gives Beam RPD peripheral vision that is comparable to a human's field of view. A digital zoom lets the op-

erator further focus on details in the remote site. Beam uses an array of six microphones and audio processing algorithms, background noise reduction and echo cancellation. This equipment gives Beam an audio-quality, which obviously goes far beyond that of an iPad. Beam uses a 17-inch screen mounted at a height of 1.58 m that allows the display of a human face at its natural size and height. Another feature that goes beyond iPad standards is the WiFi connectivity. To provide reliable and seamless WiFi connectivity, Beam uses two dual-band radios and proprietary roaming algorithms. Altogether it is obvious that Beam RPD is far more than a movable iPad. It is left to the customers to decide whether this is worth a price which is an order of magnitude higher.  VIDEO 741,  VIDEO 742,  VIDEO 744, and  VIDEO 745 introduce several of the tele-presence robots available on the market today.

65.2 Enabling Technologies

The mass consumer market is very price-sensitive, so the price of the robot is key for the success of the product among consumers. Certain guidelines used in the consumer electronics market are relevant for the domestic robot market to provide a rough estimate of cost of the robot. Let's say that you want to develop a floor-care robot that would retail at \$ 300, the *rule of thumb* is that your bill of materials (BOM) should be between 1/3–1/5 of the retail price. In other words, your BOM should be within \$ 60–\$ 100! And the BOM must include all mechanical parts, electrical parts, battery, processor, memory, motors, assembly, packaging, user manuals, etc.

Given the extreme cost constraints outlined above, this chapter focuses on enabling technologies that are viable, from the cost point of view, to be included in a mobile domestic robot with a price lower than \$ 1000 (or ideally below \$ 500). These technologies are required to have a reliability level in line with the expected life time (and warranty) of the product; otherwise, no matter how good the technology is, if it stops working in an unreasonable period of time, the robot will be returned to the retailer. Special emphasis should be placed in the ease of manufacture of the technology. Difficult to manufacture components create delays in the production line, decreasing the yield of the product and eventually increasing the overall cost of production, leading to either eroding profit margins or a rise in the retail price.

Mobile robots need to sense and understand the environment in which they operate. The first key enabler is the capability of detecting obstacles and hazards

to safely and accurately navigate around them. Section 65.2.1 describes the different available technologies for obstacle and hazard detection. The second key enabler is the ability to localize and create a map of the environment to intelligently plan actions and motions that allow the robot achieve its goal. Section 65.2.2 presents the technologies available for localization and mapping using a number of low-cost, yet powerful sensors. Section 65.2.3 discusses alternative approaches to coverage of the space implemented in commercial products.

65.2.1 Sensing and Obstacle Avoidance

Domestic robots aim to take care of tedious chores, interacting with a household that includes owners, children, babies, pets, and stationary objects such as chairs, tables, walls, etc. Domestic robots must be safe in order to gain acceptance in our daily life: it is not tolerable to have a robot falling down the stairs or hurting a household member. Thus, robots must be equipped with drop/cliff sensors and proximity sensors that ensure proper operation while still satisfying the mentioned cost constraints.

Cliff Sensors

A number of solutions are present in current robots in the market. Off-the-shelf solutions are IR sensors from Sharp that consists of an emitter (light emitting diode LED) and a receiver (photodetector or position-sensitive-device PSD) that provides an output proportional to the distance to the object. The Roomba uses

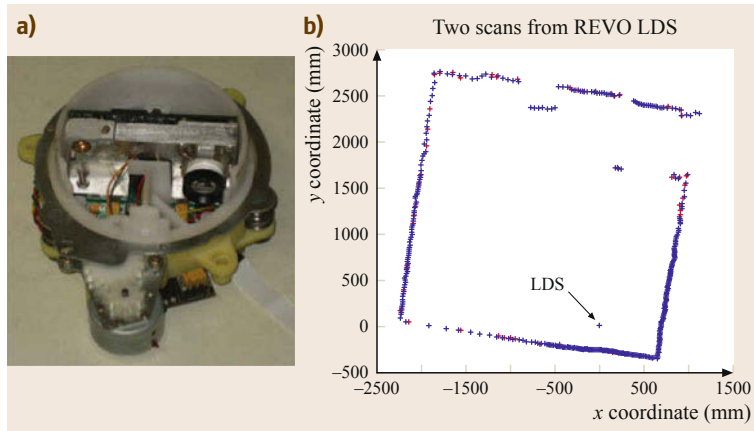

Fig. 65.14a,b Laser Distance Sensor. (a) Prototype and (b) occupancy map generated with the sensor

a custom **IR** cliff sensor based on a similar principle that trades generic distance measurement with sensor cost. The Mint robot from Evolution Robotics employs a factory-calibrated mechanical hammer that triggers upon cliff detection. Solid-state sensors are usually more reliable than mechanical sensors, since they do not have moving parts, but have the drawback of a response dependent on the reflectivity of the surface in the **IR** spectrum and a dead-band in the response.

Contact and Proximity Sensors

Mechanical switches, called *bump sensors*, are commonly used for detecting when the robot gets in contact with obstacles. Bump sensors are cost-effective solutions providing the ability to stop the robot without damaging the obstacle. Touching obstacles is not desired unless performed very gently to ensure that the robot goes under curtains and bed skirts. **IR** and sonar sensors are frequently employed as touchless alternatives to the bump sensors by measuring the distance to obstacles. Both types of sensors are composed of an emitter and a receptor with an output proportional to the measured distance. **IR** sensors are usually more focused than sonars and less sensitive to multiple reflections on walls and other obstacles, but might lose thin obstacles such as chair legs. This type of sensors provides a point-wise measurement of distance to obstacles, so a robot needs a number of these sensors to obtain a dense representation of the obstacles in the environment. The information on obstacles and hazards (cliffs) is collected in occupancy grid maps and used for decision-making in systematic cleaning robots. A number of cost-effective dense distance measuring sensors have recently appeared in the market and will be discussed in the next sections. These dense distance measuring sensors have a cost on the order of tens of dollars, while the point distance measuring sensors have cost only a few dollars, so most of the domestic

robots currently available on the market have yet to incorporate dense distance measuring sensors. The only exception is the Neato XV-21 that uses a low-cost laser distance measuring system.

Laser Distance Sensor

A low-cost Laser Distance Sensor was developed by Konolige and colleagues [65.5] using a laser point beam and a global shutter **CMOS** imaging sensor separated by a small baseline. The system operates by triangulation and achieves full 360 planar scan by rotating the optical assembly on a full circle. The sensor has a range of 0.2 to 6 m with an error < 3 cm at 6 m and an angular resolution of 1 degree, providing 4000 readings per second (up to 10 Hz) with a small size (approximate width of 10 cm shown in Fig. 65.14a) and low power (< 2 W). The sensor is eye safe and provides measurements that enable laser-based **SLAM** as shown by Fig. 65.14b.

Structured-Light Distance Sensors

Structured-light distance sensors consist of an emitter that projects a known pattern on the environment and a receptor that computes depth based on the deformation of the received pattern. The Kinect [65.6] interface to the Xbox game system uses a structured-light sensor from PrimeSense [65.7] thus showcasing the readiness of this sensor for consumer applications. The emitter consists of a laser with optics that projects a known pattern (Speckles [65.8, 9]) in near-**IR** light and a complementary metal-oxide-semiconductor (**CMOS**) **IR** camera that observes the pattern to estimate depth using triangulation. The emitter and the camera are calibrated during manufacturing assuming a rigid configuration. The speckles can be further shaped into ellipsis using optics with different focal lengths in *x* and *y* so that the orientation of the observed ellipsis is proportional to depth. Speckles of different sizes are used to obtain different depth accuracy depending on size. Figure 65.15a

shows the speckles pattern projected by the sensor and an image taken in the dark by photographer Audrey Penven showing the IR speckles. Figure 65.15b shows the components of the Kinect sensor and the corresponding RGB and depth images of a scene.

Time of Flight (TOF) Distance Sensors

Time of flight (TOF) sensors consist of a light source (usually a laser) that emits a continuous waveform and a special imaging sensor that measures the phase shift of the received signal in each pixel. The depth at each pixel is proportional to the phase shift. TOF sensors have been in the market for quite some time, but the need for allocating a large portion of the sensor to the decoding electronics has made it challenging to produce low-cost sensors at reasonable resolution. Some of the companies offering TOF sensor have been Mesa Imaging AG that produces the SwissRanger [65.10] sensors, Softkinetics [65.11], PMDvision.

Stereo Vision

Stereo vision is a well-known computer vision solution to the extraction of three-dimensional (3-D) depth maps in areas with sufficient texture to find image correspondences. As opposed to structured light or TOF sensors, stereo vision systems are totally passive, but require a calibrated stereo rig, and their performance depends on the level of external illumination and on the amount of texture present in images.

The selection of the optimal dense mapping sensor depends on the application. The laser distance sensor provides reasonable information for laser-based SLAM and obstacle detection and avoidance; however, it only provides range information on a plane as opposed to the dense 3-D range offered by the structured light, TOF, or stereo systems. The structured light sensor uses a simple imaging sensor but requires additional computation to estimate depth in each pixel while the TOF sensor computes depth in each pixel at the expense of a sensor with lower fill factor. The stereo system does not require additional lighting, but requires an additional camera and a computation module to extract depth. Other parameters to consider are the maximum and minimum range that the sensor provides to ensure that it fits the requirements of the application in terms of mapping and obstacle detection.

65.2.2 Localization and Mapping

A robot that knows its location and understands its surroundings is able to plan intelligent maneuvers to achieve its goals. Localization and mapping are basic primitives that enable smart and efficient behavior. Early successful robots like the Roomba chose to sac-

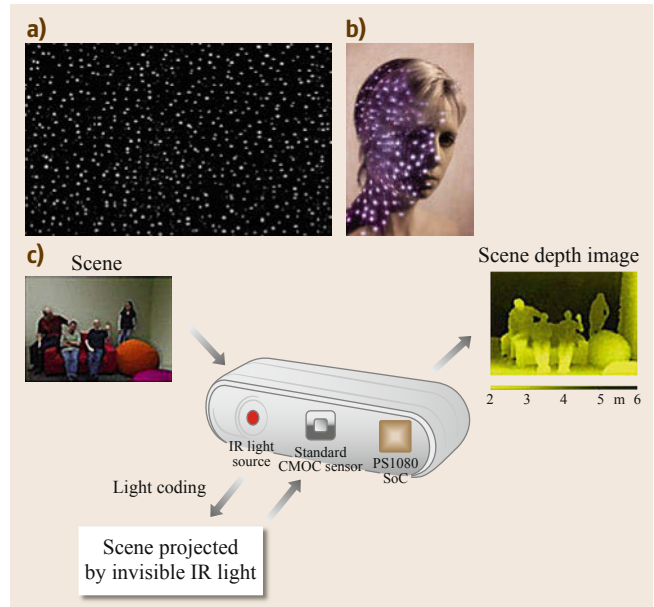

Fig.65.15a–c Primesense sensor: (a,b) Speckles pattern projected by the laser emitter. (c) Block diagram of the Kinect sensor

rific localization and mapping in order to achieve an appealing retail price since the localization and mapping technology was either too expensive or not existent at the time (many of the dense sensors presented in the previous section were developed after the Roomba). In recent years, a number of low-cost, yet powerful simultaneous localization and mapping (SLAM) technologies have been developed and integrated in floor-care products. These technologies are described in the following sections.

Vector Field SLAM

The Mint robot by Evolution Robotics uses active beacons for localization. The Northstar beacon projects two IR spots onto the ceiling that are modulated to simplify the detection of the spots with the sensor. The spots are invisible to the human eye and thus do not produce visual clutter. While placing the beacon can still be regarded as a modification to the environment, surveys among our customers suggest that the vast majority largely accepts setting up the beacon prior to running the robot [65.12]. The Northstar sensor uses 3 photodiodes to compute the direction to the spots from the measured current through the photodiodes. The photodiodes can be sampled at high frequency to detect the modulated spot frequencies for data association. The sensor is quite inexpensive and suitable for cost-sensitive applications. However, the sensor suffers from multipath since light not only reaches the sensor directly but also through reflections from walls

and other furniture, making the position computed by the sensor inadequate to be directly used for localization and mapping. The sensor is augmented with a localization method that learns the light distribution in the room through a simultaneous localization and mapping (SLAM) approach [65.13]. Figure 65.16 shows the Mint robot cleaning the environment depicting the operation of the Northstar localization system and the problem of multipath. The figure also shows the Mint robot and the Northstar cube and the Northstar sensor.

In vector field SLAM the spatial variation of continuous signals is learned and simultaneously used for localizing the robot by fusing information from dead-reckoning (odometry and gyro) and Northstar. In the following, this method is introduced and tailored toward measurements obtained from Northstar. The signal field is represented as a regular grid of fixed node positions $b_i = (b_{i,x}, b_{i,y})^T$, $i = 1 \dots N$, where each node $m_i \in R^4$ holds the expected Northstar positions of both spots when placing the robot at b_i and pointing it in a fixed orientation $\theta_0 = 0$. Vector field and robot pose are then estimated through the application of SLAM.

Let the robot path be a time series of poses $x_0 \dots x_T$, $x_t \in SE(2)$, i.e., the set of rigid transformations in the horizontal plane, and let $x_0 = (0, 0, 0)^T$. At each time step $t = 1 \dots T$ the robot receives a motion input u_t

with covariance R_t and a measurement $z_t = (z_{x1}, z_{y1}, z_{x2}, z_{y2})^T$ of the two Northstar spot positions with covariance Q_t . The spot positions are also each affected by the rotational variability denoted $c = (c_x, c_y)^T$. The rotational variability models errors in measuring the direction to the spots caused by not having the sensor perfectly level.

The SLAM problem is solved with the ESEIF-SLAM that is constant time and requires memory linear in the size of the area explored by the robot. The method has been implemented in the processor of Mint, an ARM 7 processor with 64 kByte RAM [65.13]. Vector field SLAM has been extended to address covering larger areas by using more Northstar beacons [65.15] and to provide a solution for the re-localization of the robot after it has been kidnapped or paused and resumed [65.16].

Figure 65.18 presents the map obtained by the robot after a cleaning run in a home environment of 125 m² covered by three Northstar beacons marked with the pink and green disks (units are in meters). The robot navigated in the home by following a cleaning strategy based on systematically covering sectors of the environment. As long as at least one beacon is visible to the robot, the strategy moves the robot onto a neighboring region until no space is left to clean. At the end the robot follows along the perimeter of detected obsta-

Fig. 65.17 Vector field SLAM with Northstar

Fig. 65.18 Robot map obtained with vector field SLAM in a 125 m² home environment

Fig. 65.19 (a) *cv-SLAM* (after [65.14]). (b) Features extracted by the vision front-end. Map obtained with the *EKF*

cles for a thorough cleaning around walls and furniture. As the robot moves through the environment it creates an occupancy grid map using the position information from localization. Each visited cell is classified into one of the following categories: obstacles (drawn in black), floor changes (drawn in brown), hazards (drawn in red), and free space (drawn in shades of blue that indicate visibility of the spots, the lighter the blue, the better the visibility).

Visual SLAM

Visual localization and mapping is attractive for a variety of applications due to the rich input and the low cost and footprint of visual sensors. The difficulties lie in robustly extracting a critical subset of information from the high-rate visual data stream and processing it efficiently to yield useful output. Despite steady increases in the computational power of most platforms, such challenges are nonetheless exacerbated by the limited processing and storage provided by low-cost, embedded systems appropriate for low-power applications or consumer products. Many state-of-the-art approaches to visual *SLAM* depend on a per-frame processing rate sufficiently high, relative to the speed of camera motion, to permit strong temporal assumptions on the image sequence. This section reviews two approaches to visual *SLAM* focused on domestic robots. Ceiling vision similar to the work of Jeong and Lee [65.14] can be found in the Navibot from Samsung, the Roboking from LG, and the Iclebo/Homerun from Yujin Robotics/Philips. Furthermore, visual *SLAM* systems have been developed for low-cost and embedded systems [65.17, 18].

cv-SLAM

The ceiling vision *SLAM* [65.14] system is composed of a camera facing upward, looking toward the ceiling. The system extracts corner features using a Harris detector and matches features using correlation. Feature matching achieves invariance to view point changes by training a set of multiview descriptors of the features as matching proceeds during the run. The main orientation(s) of the feature are further used as descriptors

of the feature to ensure a two-dimensional (2-D) rotation invariant feature matching that can be used for relocalization. The localization and mapping backend of the system is based on an extended Kalman filter (*EKF*) that fuses visual and dead-reckoning information (odometry and gyro) and that tracks the pose of the robot in a two-and-a-half-dimensional (2.5-D) (x , y , θ) and the 3-D position of the features (landmarks of the map). The orientation(s) of the features are also represented in 3-D and tracked with the *EKF* to predict changes in the feature patch due to motion of the robot (as the robot moves, features on the ceiling will undergo a rotation while features on the walls will experience a shearing transformation in addition to rotation).

Figure 65.19a shows corner points and their estimated orientations in views with rotation only. Figure 65.19b presents snapshots from a sequential map-building experiment on a corridor.

vSLAM

The *vSLAM* [65.17, 18] system from Evolution Robotics is designed for a low-cost robotic platform equipped with simple odometry and a single camera. Figure 65.20 shows the block diagram of the system. Operating primarily as a view recognition engine, the visual measurement front-end requires only occasional, weak assumptions on processing rate, and intrinsically provides robust loop closing when previously mapped areas are revisited. The visual measurements and odometry are fused in the back-end in a graph representation and optimized incrementally. The *SLAM* graph complexity is bounded during operation using variable elimination and constraint pruning, with heuristic schedules in order to keep optimization and storage costs commensurate with explored area, rather than with time of exploration, all while causing minimal loss in mapping and localization accuracy. The system has been evaluated on real datasets with planar ground-truth reference, showing that the system operates successfully even at frame rates below 2 Hz, running on an ARM9 processor with 64 MB of *RAM* [65.18].

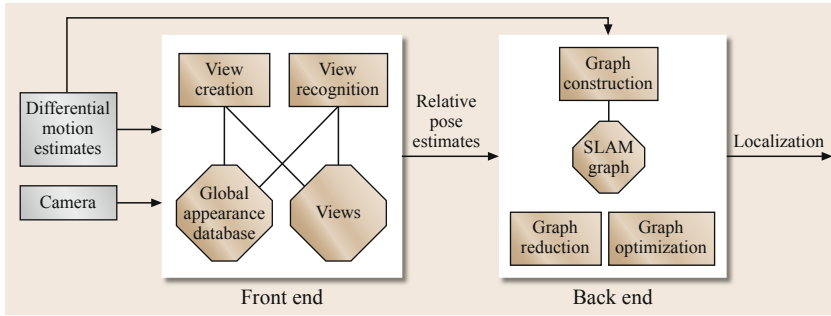

Fig. 65.20 vSLAM block diagram

View recognition engines [65.17–22] have proven attractive components for SLAM systems because they permit robust and flexible loop closing. Instead of making correspondences between individual features or measurements as in the *cv-SLAM* system, view recognition engines typically match constellations of features or entire images, without requiring tracking. vSLAM [65.17] creates views by first matching SIFT [65.23] features on pairs of incoming images, and second computing structure and motions estimates using bundle adjustment. The SIFT features are stored in a local database for each view and on a global database for the complete map. View recognition is performed by a feature lookup in the global database that provides a set of candidate view matches. Feature lookup in the local view database followed by robust outlier rejection and a local bundle adjustment completes the view recognition and visual pose estimation process.

Commonly used graph SLAM methods for agglomerating sensor information often incur computation and storage costs that grow with time, rather than with space explored. For a robot operating for extended periods within a limited spatial area – typical of practical applications – this is an undesirable trade-off. vSLAM [65.18] instead applies probabilistically sound graph reduction methods that limit the complexity of the graph to a linear factor of the complexity of the explored space. Past poses of the robot that are not used for view recognition can be marginalized out of the estimation, and their incident constraints are collapsed back into the graph.

Figure 65.21 presents the results of running the vSLAM system in two sequences, one collected in a regular household (*right*) (same house as the one shown in Fig. 65.18 for vector field SLAM) and the other collected in a large warehouse environment (*left*). The first set of plots show the ground truth path of

Fig. 65.21 vSLAM results on a warehouse environment and in a household environment

Fig. 65.22 Map created with the Neato XV-11 robot (www.youtube.com/watch?v=zodC8EFvh7g)

the robot and the floor plan of the environments. The second set of plots shows the trajectory of the robot estimated with vSLAM. The warehouse environment extends over an area of 24×12 m and the house over an area of 20×9 m. The estimated trajectory has a root mean square (RMS) error of 44 cm in the warehouse case and of 28 cm in the household case.

Laser-Based SLAM

The previous sections presented a number of low-cost solutions to the SLAM problem in which the data association was (almost) perfect. In the case of Vector-Field SLAM, the modulation of the spots of the Northstar cube ensures a unique identification of the spot. In the case of visual SLAM, the visual front-end incorporates a number of checks to ensure that misrecognitions are very rare. Laser-based SLAM has the characteristic that the measurements acquired with the laser are not unique since it is possible to obtain similar measurements in a variety of places in a household (just aiming the laser to a wall will provide measurements that are indistinguishable from a measurement to a different wall). In addition to the data association problem, laser distance measurement sensors, such as the one presented in Sect. 65.2.1, provide both range and bearing to the landmarks. Both Northstar and cameras give only bearing measurements to the spots or features.

The laser-based SLAM literature is quite extensive [65.25]. The estimation back-end could be an

extended Kalman filter (EKF), a Particle Filter, or a GraphSLAM system. Several data association algorithms are available, some of them are proactive (or even greedy) [65.26, 27] and some are lazy [65.28] in assigning correspondences between measurements and landmarks. The selection of the algorithm to implement in the domestic robot would be guided by the trade-off between computational resources and the performance requirements. Figure 65.22 presents a map obtained with the Neato XV-11 robot.

65.2.3 Navigation and Coverage

The Trilobite robot vacuum cleaner by Electrolux was one of the pioneer robots to be commercialized. The trilobite was equipped with a sophisticated custom sonar sensor system that allowed the robot to navigate without touching obstacles (or touching them very gently). The coverage strategy consisted of two stages: first, explore the perimeter of the room to estimate the area to clean and second, cover the room with wall-to-wall diagonal passes. The perimeter exploration stage assumes that the robot would eventually traverse through the complete boundary of the area to clean and return to the charging station (Fig. 65.23a).

As mentioned previously, the cost constraints forced early robots like the Roomba to eschew advanced features like localization and mapping in order to offer a product at a price point accepted by consumers. Nevertheless, the navigation strategy implemented in the Roomba was quite effective in covering the space, especially when running in single rooms or in presence of large amount of clutter. The Roomba uses a spiral pattern in open area to optimally cover the space without localization until it hits an obstacle (Fig. 65.23b). Then it selects random orientation and continues moving in straight line until reaching the next obstacle where it selects another random orientation to continue with the same behavior. The spiral can be triggered when the robot travels for a certain distance without having found any obstacles. Many of the other random robots present in the market have a strategy that follows similar principles to the Roomba one.

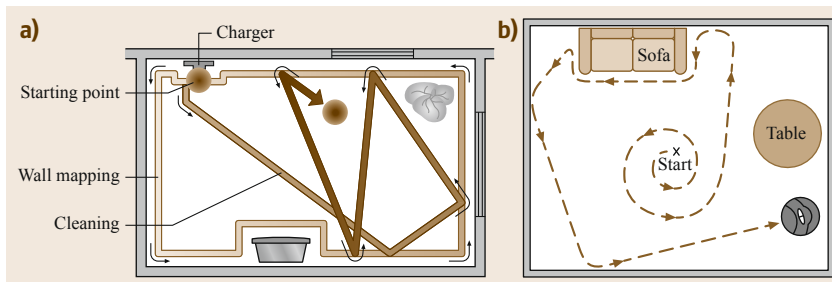

Fig. 65.23a,b Coverage strategies. Trilobite strategy. Roomba strategy [65.24]

Fig.65.24a–c Long exposure images [65.29] showing the coverage strategies of the (a) Roomba, (b) Neato, and (c) Mint

Fig.65.25a,b Coverage strategies for lawnmowers. (a) Tango [65.30] by John Deere and (b) Indego [65.31] by Bosch

The systematic robots on the other hand take advantage of the localization system to plan efficient cleaning paths to maximize coverage in the least amount of time, pause for charging on the docking station and resume cleaning from the last cleaned spot, and intelligently navigate from room to room. Mint takes the strategy of focusing first on open area cleaning, covering the space in parallel straight passes to traverse as much open space as fast as possible, and then performing a final cleaning on the perimeter and around the obstacles. This perimeter cleaning step enables Mint to uncover portals to new areas that were not encountered during open area cleaning. Other robots like the Navibot from Samsung, the Roboking from LG and the iClebo from Yujin/Philips use a similar strategy without the final perimeter cleaning. The Neato XV-11, on the other hand, performs first an exploration and cleaning of the perimeter of the environment in order to create a good localization map and then completes the coverage of the open area. Figure 65.24 shows long exposure pictures of different robots: Roomba, Neato, Mint sweeping and

Mint mopping. These long exposure pictures show the trajectory of the robots during normal cleaning operation.

The lawnmower robots use similar coverage strategies to the ones of vacuum cleaner robots. One element common to all lawnmower robots is the usage of an embedded wire to define the perimeter of the lawn. Within the boundaries defined by the wire, some robots like the Automower from Husqvarna or the Robomow from Friendly Robotics use a complete random coverage strategy. The Tango from John Deere combines straight motions in random directions with spiral motions (a-la-Roomba). The Indego from Bosch is the only robot that attempts to systematically cover the space by first exploring the perimeter to estimate the size of the lawn and then traversing the interior with parallel straight passes. Systematic coverage is enabled by fusing sensory information from wheel odometry and an inertial measurement unit (IMU) by means of probabilistic reasoning with prior knowledge. Figure 65.25 depicts the coverage strategies of the Tango and the Indego.

65.3 Smart Homes

Several attempts have been made in the literature to define the term smart home, for example, in [65.32] the term is defined as *the latest expression of the various ways in which technology in the home has developed*. In [65.33], the notion of a smart home is defined more explicitly as:

a residence equipped with computing and information technology which anticipates and responds to the needs of the occupants, working to promote their comfort, convenience, security and entertainment through management of technology within the home and connections to the world beyond.

Smart homes typically comprise elements such as network of sensors and actuators, and also entire robotic systems.

In 1999, a company called e2 Home was established by Ericsson and Electrolux to explore the possibilities of smart homes [65.34]. E2 Home built several houses with smart home devices using IT technologies. Through the exploration, several issues relating to smart homes from business point of view have been unveiled, which include the difficulties relating to the complexity of the system, starting up the new business model, handling of intellectual property rights (IPR) for the third parties contents, and the consumer's needs. The company was liquidated in 2004.

Current smart home technology includes video monitoring, motion detectors, fall detectors, pressure mats, environment control, health monitoring such as blood pressure, pulse rate, body temperature, weight, and human computer interaction (HCI) technology, for example, to recognize gestures. Smart homes also often refer to houses connected to a smart grid, which is defined as [65.35]:

a developing network of new technologies, equipment, and controls working together to respond immediately to our 21st century demand for electricity.

In this case, the smart home is defined as [65.35]:

a residence with the capability of efficiently controlling generated solar energy and power consumption making it ideal for vehicle power supply and management.

The development of smart homes requires a number of technical questions and challenges to be addressed [65.32]: how to convert current home structures and architectures into smart homes, how to standardize smart home components, for example, sensor networks, how to keep the equipment cost at a reasonable level, and how to deal with security and privacy issues.

In the following sections we will describe a number of prominent smart home developments, the Aware Home at Georgia Institute of Technology, the Gator Tech Smart House at the University of Florida, and the sensorized environment for life (SELF) at AIST (the Japan National Institute of Advanced Industrial Science and Technology) (Figs. 65.26, 65.27). These developments show that current smart home technology goes significantly beyond existing home automation. Accounting for the significant increase in the elderly population in the near future, many of today's smart home developments pay special attention to improving the quality of life of elderly people. The

descriptions below will also address the question on how to integrate robotics systems into smart home concepts.

65.3.1 Gator Tech Smart House

The Gator Tech Smart House (Fig. 65.26) was built at the University of Florida [65.36]. It addresses the needs of elderly people to live independently and maintain dignity and quality of life at older ages. The house is equipped with many smart devices such as smart floors, tracking the motion of the occupants of the house, smart blinds, automatically adjusting ambient light, smart display, smart cameras, smart phones that can act as a remote control to other appliances, location tracking, smart leak detectors, and smart beds. The exterior of the house has a smart mailbox which alerts residence if mail is delivered and a smart front door which can sense home owners using an radio frequency identification (RFID) tag, allowing keyless entry to home owners.

The kitchen of the Gator Tech Smart House includes a smart microwave, which uses RFID on food packages. This allows the microwave to adjust the settings for cooking the meal. It also informs the resident about the readiness of the meal. The kitchen further comprises a smart refrigerator that monitors food availability and consumption, and detects expired food items. The smart refrigerator can create shopping lists automatically and has an integrated meal preparation advisor based on items in the refrigerator and pantry.

The implementation of such a complex system has raised a number of technical issues and questions, including the development of the smart devices, data handling of networks of sensors, and interconnecting smart devices to other devices in the environment. These questions led to some new research tracks on smart houses, primarily grouped into pervasive computing and mobile computing network research.

Fig. 65.26 Georgia Institute of Technology: Aware Home

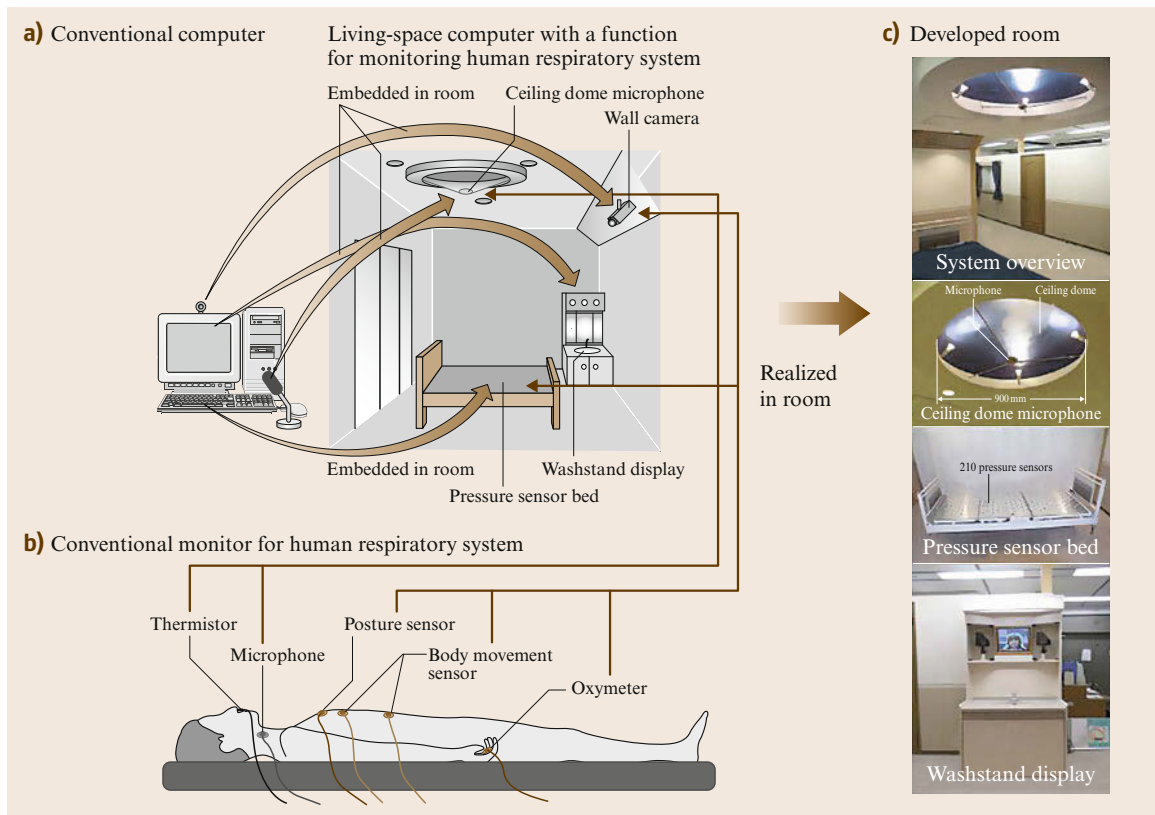

Fig. 65.27 AIST, the sensorized environment for life

65.3.2 Aware Home

Aware Home is a living laboratory for research in ubiquitous computing for everyday activities. This project is conducted at Georgia Institute of Technology [65.37]. The major objective of the Aware Home project is to build an environment that is capable of being aware and keeping track of the states and activities of its inhabitants. Aware Home creates a partnership between the resident and the surrounding sensing and computing technologies. This opens several fields of research, not only from the technology point of view, but also in terms of the social aspects of the inhabitants. The main research agenda of Aware Home spans human-centered and technology-centered research, software engineering, and social implications.

Technology and application-centered research focuses on sensor networks, distributed computing, context awareness and ubiquitous sensing, individual interaction with the home, smart floors, and finding lost objects. Research on context awareness is inspired by the fact that humans communicate with each other very successfully by referring to what is called shared

context. For communication between humans and computer systems, this shared context must be made explicitly. Sensor systems, which facilitate the extraction of context, need to be developed.

This human-centered research focuses on support for the elderly and other social issues. A key concept in supporting the elderly is *aging in place*. Aware Home is designed to support the elderly and allow them to be independent instead of moving to elderly care facilities. Supporting the elderly leads to the study on cognitive support such as reminding them when to take medication, guiding them when they lose their way, and locating lost items.

65.3.3 SELF – Sensorized Environment for LiFe

SELF stands for Sensorized Environment for LiFe [65.1]. The objectives of SELF are to develop a network of sensors which are embedded in the environment, information gathering using the networked sensors, storing and analyzing the information, and the reporting of useful information to assist and maintain good health. The basic advantages

of **SELF**, due to the embedded nature of the sensors are:

1. No limit on size, weight, or power source,
2. It does not disturb the human,
3. It does not impose physical restrictions, and
4. Sensors are rarely broken since they are fixed to the environment.

SELF can be viewed as a system that monitors a person's behavior or activity and represents the data objectively in an approach known as self-externalization. **SELF** is motivated by the fact that humans sometimes cannot notice a change in their condition which affects their health without a medical doctor. Therefore, the use of network sensors to monitor human behavior and re-

port useful information that greatly affects the health status will further improve quality of life.

The **SELF** study considers behavior as a means of communication, and sensors embedded into the environment as one way to observe a person's behavior. The **SELF** implementation consists of a bed with a sensor, a ceiling with microphones, a washstand with a display, etc. The bed with sensors can determine the time the subject sleeps and wakes up, their posture during sleeping, and their breathing pattern. The microphones attached to the ceiling can detect snoring or normal breathing sounds. Based on the monitored data, the washstand display is used as an output device to provide the subject's health status and thus create feedback to the subject.

66. Robotics Competitions and Challenges

Daniele Nardi, Jonathan Roberts, Manuela Veloso, Luke Fletcher

This chapter explores the use of competitions to accelerate robotics research and promote science, technology, engineering, and mathematics (STEM) education. We argue that the field of robotics is particularly well suited to innovation through competitions. Two broad categories of robot competition are used to frame the discussion: human-inspired competitions and task-based challenges. Human-inspired robot competitions, of which the majority are sports contests, quickly move through platform development to focus on problem solving and test through game play. Task-based challenges attempt to attract participants by presenting a high aim for a robotic system. The contest can then be tuned, as required, to maintain motivation and ensure that the progress is made. Three case studies of robot competitions are presented, namely robot soccer, the UAV challenge, and the DARPA (Defense Advanced Research Projects Agency) grand challenges. The case studies serve to explore from the point of view of organizers and participants, the benefits and limitations of competitions, and what makes a good robot competition.

This chapter ends with some concluding remarks on the natural convergence of human-inspired competitions and task-based challenges

in the promotion of STEM education, research, and vocations.

The idea of promoting science and technology through competitions became pervasive at the end of the 20th century [66.1]. Since then, competitions have been promoted in several fields, taking a broad range of formats,

goals, and target audiences. The main aims underlying this trend are to create a motivating framework for science and technology, and to support the development of skills, ideas, and technical solutions.

66.1 Introduction

These objectives fit particularly well with the field of robotics, since the design and implementation of robots is a great challenge for a competition. Robots are physical artifacts, whose design and implementation require creativity, technical skills, and scientific knowledge. Arguably, Robotics is nowadays the field where competitions have the strongest impact.

The competitions that aim at the design and implementation of robots cover the whole spectrum of the educational chain, from young pupils of the elementary schools to senior researchers, such as the authors of this chapter. Moreover, there is a large world of hobby robot competitions, that we will not specifically address in this chapter. The focus of this chapter are those initiatives that are specifically targeting autonomous robotics research and education.

Another ingredient that makes robotic competitions very successful is that robotics requires a great deal of integration. Consequently, building a winning team requires a substantial cooperation among team members with very different skills and backgrounds. This creates an ideal playground to address teamwork within educational programs, and an engineering challenge for higher level students and researchers. The level of per-

formance that robots achieve in the competitions is often compelling, as compared with the prototypes that are developed within conventional research projects. In this respect, competitions provide an outstanding testbed for scientific and technical solutions.

Robotic competitions can have great appeal for a general audience; thus, robotic competitions are also a very effective tool to bridge the gap between citizens and the progress of science and technology.

There are several features that can be used for the classification and presentation of competitions. We have chosen to distinguish between competitions where the contest mirrors a traditional human contest and competitions where robots are challenged to perform some task. The task whose achievement, once mature, would extend the possible uses of robots in our society.

Next we present an overview including past robot competitions and considerations that apply across all robot contests. We then focus on human-inspired contests with a case study on robot soccer. Later we review task-orientated contests with case studies on the UAV challenge and the DARPA grand challenges. The chapter ends with concluding remarks on lessons learned thus far in robot competitions.

66.2 Overview

The history of robot competition begins with the Micromouse contests. In 1977, the IEEE Spectrum magazine announced their intention to hold an *Amazing Micromouse Competition*. The contest took the form of a time trial where a small wheeled robot *mouse* raced to complete a maze in the shortest possible time. The first event to be held was in New York in 1979 and saw over 6000 entries. However, the field rapidly shrank to 15 competing *mice*. This first contest of these early autonomous robots was won by a simple wall-following robot. While a valid victory, the rules for future events were swiftly changed to move the goal point from the edge of the maze to the center, ensuring that the path search aspect of the problem was emphasized [66.2]. The micromouse contest then became very popular across Europe, then later Japan and then back to the USA by the mid-1980s. Micromouse events continue to be held to this day, including contests from India and South Korea. The contest which began as a struggle to develop a device that could reliably traverse corridors without jamming, is now a highly optimized contest where precision machines complete the maze in under 5 s [66.3].

Seeing the success of the micromouse competition and the power to inspire science and technology ed-

ucation, Dean Kamen conceived the For Inspiration and Recognition of Science and Technology or *FIRST* robot competition. In the *FIRST* robot competitions high school teams would compete to build and program a robot to complete a challenge. The original challenge in 1992, titled *Maize Craze*, involved herding balls into a home goal. Since then the challenge, from stacking containers to throwing flying discs, has been changed year to year while keeping the basic structure of the contest the same. The contest, like the Micromouse contests, have expanded internationally and continue to this day. In 2014, the competition is projected to involve 68 000 students [66.4].

Meanwhile, in the early 1990s, the advances and limitations of game playing computers, and the need to evaluate competing algorithms in mobile robotics converged toward the concept of a new competition for academic robotics: robot soccer [66.5–7]. We will continue this discussion in Sect. 66.3.

In 1995, restlessness at the pace of innovative change since the space race of the 1960s sparked aerospace entrepreneur Peter Diamandis to propose the X-Prize. Ansari X-Prize was a \$10 million prize to demonstrate a functional privately developed space pas-

senger plane [66.8]. Rekindling the idea of racing to achieve an ambitious task was captivating and caused ripples through the scientific community [66.1]. The inspiration spread to other fields and funding bodies resulting in many initiatives such as the UAV challenge and the [DARPA](#) grand challenge which we discuss in Sect. 66.4.

Robotics is well suited to innovation through competition. As this handbook testifies the field of robotics is broad and covers research in mechanical design, electronics, control theory, signal processing, software engineering, and machine learning to name a few. In addition to the breadth of the field the nature of the research also requires one or more agents interacting with the physical environment, thereby limiting the use of techniques common to other technical fields to share and validate their research.

Standard techniques such as: standardized tests (which are commonplace in science and engineering), shared test data sets (such as those used in image processing and machine learning communities), and reference implementations (used in computer science algorithm evaluation) are invaluable in robotics but cannot cover the full scope of a robot system operating in the world. Indeed, many components used in robotic systems can be tested in isolation with these same techniques; however, as the components of a robot are integrated into a system of systems interacting with the physical world the limits of the above methods becomes evident. In terms of test methodology: unit and integration level testing are well served; however, system, dynamic and, in particular, acceptance testing of innovation across the field was missing. An answer came in a resurgence back to the roots of robotics and in favor of robot competitions.

The range of robot scientific competitions is very broad, and in this section we look at them from different perspectives, aiming at providing an overview of the settings that have been developed so far. To this end, in the following we address a number of aspects that are relevant to the design and implementation of a robot competition.

66.2.1 Aims and Targeted Participants

As suggested in the introduction, the competitions that are addressed in this chapter are those focussed on research and education. These two aspects are often deeply inter-related. On one hand, there is always an educational component in any research involving a team with different backgrounds and different levels of expertise. Moreover, if one looks at competitions as an educational tool, they represent one of the most advanced forms of education; consequently, they specifically at-

tract teachers and mentors that are involved in research on education. Although research and education are related to one another, the balance between research and education is naturally significantly different across the numerous robot competitions.

66.2.2 Competition Challenges

Each competition relies on a challenge and there are several ways of categorizing them. While competitions are nowadays mostly among robots and not robot-vs-human, a large group of competitions take inspiration from human competitions, ranging from soccer, to the Olympic Games. These competitions have an explicit or implicit underlying assumption of comparing robot performance with human performance. The other kind of challenge aims at a proposing a specific problem to be addressed using machines the hope is that by racing to achieve the aim, new capabilities can be matured faster into future robots.

66.2.3 Types of Robots

Another key element for classification of competitions is the robot type. Any kind of robot is conceivable for use in competition. Robot choice is driven by the competition format and targeted participants. The use of commercially available robots and robot kits enables less mechanically focused participants to move forward quickly. The use of homogeneous sets of robots enables competitions to be fought on algorithmic innovations over robot manufacturing skill. An unrestricted category of robot type can be useful for some task-based challenges, where a novel physical design may be the key in simplifying the problem and achieving the objective (such as in rescue robotics).

66.2.4 Competition Scenarios

The scenario is largely determined by the challenge addressed, be it a competition among soccer robots or among service robots operating in a home environment; consequently, there is a broad variety. In some cases, the scenario is fixed and known before the competition, such as in robot soccer; in other cases, only a general description is provided beforehand and the actual competition scenario is not known in advance as, for example, in search and rescue competitions. The competition scenario has deep implications not only on the setup of competition venues, but also on the participating teams. Practice environments for teams in lead up to competition must be representative, while not prohibitive to construct. From Lego robot soccer to the [DARPA](#) Robot challenge simple readily available hard-

ware store materials have been the material of choice for contest environments.

66.2.5 Safety

In some cases, the competition raises safety issues for the participants. This is the case for example of UAV competitions, and proper measures need to be taken in order to ensure a satisfactory level of safety. Moreover, the organizers must carefully address regulations for deployment of unmanned vehicles and/or use restricted access areas for the competition.

66.2.6 Qualification

Competitions with a large number of participants, such as education programs, can require regional and qualifying rounds similar to traditional sports leagues. When contests require a substantial effort and expense to participate funding agencies may make grants available to teams which succeed at a qualifying round to contribute to the cost to compete. Diverse selection criteria for satisfactory progress may well be considered in this case including justification of sound financial backing to complete the competition.

66.2.7 Evaluation

Evaluation is one of the key features of competitions both in terms of education (students must deliver a working solution) and in terms of research, where the integration of components is not a straightforward engineering practice. However, competitions also provide a great opportunity for developing benchmarks and new test methods: performance evaluation is an open issue in robotics and competitions are providing significant insights into the development of reliable and repeatable measures and testbeds.

66.2.8 Organization

Competitions are typically originated by a perceived need by a related scientific interest group, such as

a conference (e.g., AAAI, ICRA), a research funding agency (e.g., DARPA, ESA) or an entrepreneurial private company. Once established an ongoing competition founded by the first two groups will often be ran through a dedicated not-for-profit foundation. However, increasingly, education is a large business and competitions are becoming a significant activity therein; moreover, companies that help running competitions as projects are now on the market and production companies are now looking at competitions as viable tools for beyond state-of-the-art product development (not restricted to robotics) and for promoting their products.

66.2.9 Sponsors

The organization of a competition requires a substantial effort and budget. There are, however, several sources for acquiring the necessary resources. A first category of sponsors are schools that undertake competitions as part of their educational activity. The other natural sponsor are the funding agencies that institutionally provide support to research in robotics. The involvement of funding agencies can be many fold, ranging from the whole creation of a competition to the support of specific event, in particular at the local level. Another kind of sponsorship comes from public institutions that may regard competitions as a mean to drive citizens' attention on scientific and technological development. Robot manufacturers are also interested in sponsoring competitions that promote the use of their products. Besides promoting specific competitions, companies are also generally interested in supporting competitions as a form of advertisement. This is obviously related to the kind of visibility competitions can reach on the media. Moreover, companies may sponsor teams of young students as a form of recruitment and supporting education.

As the earlier discussion shows, a successful robotic competition not only requires to put forward a grand challenge or target specific societal needs, but it also requires a careful design and implementation.

66.3 Competitions Inspired by Human Competitions

In this section, we focus on competitions among robots that take inspiration from human competitions. The challenges that have been driving a lot of research in Artificial Intelligence, such as chess, go, checkers, are inspired by human competitions/games, but they do not address the interaction with physical world. On

the other hand, robotic competitions that are inspired by human competitions are typically connected with sports. A variety of sports have been addressed, from Olympic games [66.9, 10], to robot soccer [66.11, 12], to other competitions, such as sailing [66.13] or racing [66.14].

The distinguishing feature of this category of competitions is the grand challenge not only of emulating human performance, but to do this in the context of a human competition. Consequently, the robot is in principle humanoid, although several other platforms have been used, creating games for robots on wheels, given that, at this stage, it is a much simpler and accessible locomotion. It is worth noticing that a big push to this kind of competitions was given by companies such as Sony or Honda, which developed humanoid platforms also as showcases of their research and development activities.

One additional challenge that characterizes the human-inspired competitions is that several of them involve multiple robots. This feature has several significant consequences, not only in terms of the requirements on the teamwork among the robots, but also on the teamwork of the development team.

The scenario of these competitions is mostly outdoor; however, due to both technological and practical reasons often they take place indoor. On the one hand, platforms that are waterproof, work on grass or uneven terrain are unavailable or much more difficult to realize; on the other hand, practical considerations suggest to keep participation affordable and accessible.

One important feature of human-inspired competitions is that they aim also at providing some entertainment for the general public. Therefore, a suitable balance between technical difficulties and level of performance is needed. It is worth noticing how the general public is more keen to accepting the limitations of robots in playing soccer than in accomplishing a mission in Fukushima plant. Consequently, even games with slow and somewhat disappointing performance can generate participation, interest, and even strong emotions in the audience.

Human-inspired competitions span over the whole spectrum of participants, including both research oriented and more educational targets. In all cases, the type of competition creates an interest both in young generations that are naturally attracted by their ludic character, and in more mature researchers that aim toward the scientific challenges that they embody. A consequence of the intuitive appeal exerted by human-inspired competitions is that they easily attract large numbers of participants. Indeed, a frequent pattern of participation is to start with games and then move to other kinds of competitions that target socially or business relevant goals. In some cases, this endeavor is encouraged by the presence in the same event of both types of competitions.

The evaluation of the performance, in the case of human-inspired competitions, is very clear and amounts to winning the game. There are, however, examples of

specific capabilities associated with the game that are individually evaluated.

Given the reference provided by human competitions, human-inspired robot competitions typically have a permanent nature and a structure with local qualifying events. Consequently, there is an organization body managing the competition across the years and the main ones are nonprofit organizations (NPO)s. There are, however, commercial opportunities and companies that are interested in the deployment and sale of their robots. At present, these companies are mostly sponsoring the events, and often provide special offers for their products to the teams that enter the competition.

As mentioned earlier, human-inspired competitions have a strong appeal to the general public. Consequently, public organization often endorse and support them within their initiatives aiming at public awareness and promotion of science and technology. According to a common pattern, this may also attract large companies that invest some of their marketing budget in supporting socially and scientifically targeted events.

The ultimate consequence of the above sketched scenario is that the human-inspired competitions have a large impact on the general public. We have seen reports on human-inspired competitions in the media not only in the sections that typically cover science and technology, but also in the general news, and sometimes, even in connection with sport reports.

Besides this somewhat indirect effect, there are two major direct impacts of human-inspired competitions: on education and research. The renovation and advancement of the school system is embracing competitions for two major reasons: they motivate pupils and they teach key skills that are typically not addressed by conventional curricular activities. Human-inspired robotic competition perfectly fit both purposes. As for research, the scientific challenges, that have been put forward, whether or not they will turn out to be too ambitious, have gathered the attention of significant number of researchers, have driven a large body of research and have given rise to a number of side-effect developments: they are therefore fulfilling a role that is nowadays essential in the overall effort for advancing science and technology.

Robot soccer has a significant role within this category of competitions. The idea of robot soccer was discussed by several researchers in the early 1990s [66.5, 6]. Shortly afterward, Robot soccer competitions have been designed, in several venues, including Federation of International Robot-soccer Association (FIRA) [66.11, 15] and RoboCup [66.7, 12, 16].

In the next section, we address in more detail the RoboCup competitions. RoboCup remarkably started with the statement of a challenge, by *Hiroaki Kitano* and the initial RoboCup cofounders [66.7], namely

Table 66.1 Five subleagues of the RoboCup soccer games

League	Soccer players	Perception	Reasoning	Actuation	Communication
Simulation (Fig. 66.1)	(11) Software agents, 2-D (two-dimensional) and 3-D (three-dimensional) biped	Server engine	Client per team	Physical motion and perception	Explicit
Small-size (Fig. 66.2)	(5) Custom-built wheeled robots	Centralized overhead camera	Centralized offboard	Fast ball/robot speed, kicking, dribbling, passes, goal shots	Dedicated Radio
Middle-size (Fig. 66.2)	(5) Custom-built wheeled robots	Onboard, omnidirectional	Large-space control	Kicking, goal defense	Dedicated WiFi
Standard platform (SPL) (Fig. 66.3)	(5) Purchased legged robots	Onboard, directional range	Distributed	Legged, kicking, goal defense	Dedicated WiFi
Humanoid (Fig. 66.4)	(3,4,5) Custom-built, or purchased, biped multisized robots	Onboard, directional range	Distributed	Legged, kicking, goal defense	Dedicated WiFi

that *By the year 2050, there would be a robot soccer team that would be able to beat the human World Cup team*. With such long-term goal, RoboCup is an ongoing competition, that aims at research, educational, and engineering challenges through a set of testbeds that implement soccer games among robots. The competition keeps evolving every year, by yearly evaluating the performances of the robots and generating roadmaps toward its goal.

66.3.1 Case Study: Robot Soccer

The first organized RoboCup competitions took place in 1997 [66.16], and significant progress is noted every year. Interestingly, starting in 2007, and yearly thereafter, a team of five human players (volunteers from the RoboCup Board of Trustees) plays a demonstration game with the best robot team of the middle-size league, which we introduce below. Furthermore, each RoboCup competition event includes a symposium, which highlights research and development contributions relevant to the RoboCup competitions, and also to general robotics problems. As of 2014, the robots can play the basics of the game, with great speed and accuracy, but are clearly largely noncompetitive with human players. There is still a long way to go for RoboCup to reach its goal, but RoboCup continues to achieve annually increasing success, scope, and wide participation.

RoboCup soccer games are structured in five subleagues, where robots have different sizes and different capabilities, as overviewed (Table 66.1).

Many scientific challenges are addressed through different league settings, including teamwork and strategic decision making, in particular with systems of multiple robots in adversarial environments. To this end, the setup of each competition has evolved along the years from the initial proposal [66.7]. The simulation, small-size, and middle-size leagues were the

initial leagues in 1997. The standard platform league, started as a demonstration in 1998 and as a competition in 1999, was played with the Sony AIBO quadruped robots until 2007, and since 2008 with the Aldebaran NAO robots. Finally, the Humanoid Robot League started in 2000 with team-built biped robots that could barely stand on one leg to kick, probably to the most compelling derivative in improvement, leading into 2012 to biped robots of a variety of sizes that play complete games.

We now briefly describe the individual goals and set up of the soccer leagues, aiming at discussing the technical challenges and solutions devised. A summary of the complete technical contributions is found in the RoboCup symposia proceedings [66.16–32] (VIDEO 385).

Simulation

The RoboCup simulation league was developed from the very beginning of RoboCup, as an 11-player two-team simulation server environment, the SoccerServer, conceived and implemented by Noda [66.33]. The simulation league consists of a client-server architecture in which each of the two client teams is given, as an input by the SoccerServer, the state of the game (players state and ball position), and generates actions for the simulated robots, which are passed to the server for simulation of the new state of the world. Given the controlled realistic simulated environment, the goal of the league is to enable the researchers to abstract from the complications of real hardware and focus on teamwork architectures and coordination, strategic decision making, and learning in complete teams of 11 players. Initially, the league was a 2-D simulation, and since 2009, and following its roadmap to the RoboCup goal, it was extended to include a 3-D competition, leading to the current two subleagues: the 2-D and 3-D Simulation Leagues (Fig. 66.1).

Fig.66.1a,b Simulation leagues: (a) 2-D and (b) 3-D

Fig.66.2a,b RoboCup soccer leagues: (a) small-size robots and (b) middle-size robots

In the 2-D simulation subleague, the SoccerServer simplifies the environment by representing robots as basic circular elements, though with orientation and different capabilities in terms of perception and actuation. The client teams focus on effective team composition and on the strategic aspects of the game. In the 3-D Simulation subleague, the players are simulated biped humanoids. The teams need to address low-level control of such humanoid robots, including the creation of their basic behaviors, such as biped walking, running, kicking, turning, and standing up. In addition, the teams design and implement multi-agent higher level behaviors for realistic humanoid robot teams. The 3-D simulation league is currently tightly connected to the standard platform league, as the simulated humanoid robots are based on the characteristics of the Aldebaran NAO humanoid robots, as used in the RoboCup standard platform league (see in the following). The goal is to directly transfer techniques and approaches from simulation into real robots. Both the 2-D and 3-D servers are open software projects.

Small Size

The RoboCup small-size league (SSL) has been in place since the initial RoboCup in 1997. The league is set up as a field of predefined dimensions for teams of custom soccer robots of predefined small dimensions. Initially the teams were of three robots, and later have been increased to five robots. The initial playing field was a green ping-pong table, which was selected pragmatically by the founders in 1996, in order to make the specifications of the newly created RoboCup competi-

tion accessible to any research team in the world. A few years later, the field became green carpeted with white line markings, and its size has incrementally grown to the recently increased size of 6 m × 9 m. Since its beginning, the game is played with an orange golf ball and an overhead vision system. Robots are custom built according to the specifications of the league, currently to fit within a 180 mm diameter circle, no higher than 15 cm (Fig. 66.2).

The teams are allowed to use at least one camera overhead of the field. Robots have colored marks on their tops to enable visual identification and tracking. Off-board computation by each team uses the processed images to plan and then wirelessly communicate the team actions as the motion of the small robots on the field. The RoboCup SSL league offers challenges and significant contributions in: hardware design, colored-based real-time image processing (of the colored ball and colored marker identifiers of the robots), and in team strategy planning.

The RoboCup SSL robot hardware has evolved from the early simple and brittle robots in 1997 to the sophisticated, fast, robust, kicking, and dribbling, omnidirectional robot platforms of the current days. The hardware of the RoboCup SSL clearly pioneers small robot design, in contrast with all other much larger research robots in other applications. The league also significantly evolved in the vision processing and the playing strategy. Although the global view of the complete playing field is a clear advantage in capturing a complete view of the position of all the players and ball, it proved to be quite challenging to process in real time at 60 Hz, 10 fast moving robots, and a small orange

golf ball. As the league evolved, and some teams succeeded in devising vision processing algorithms, since 2010 such solutions became a shared vision system as part of the league setup that can be used by any team [66.34]. This [SSL](#) vision is available to all researchers and can be set to be used in other applications that may need global overhead perception. In terms of strategy, the teams aimed at passing and positioning well on the field since the beginning of the league. Both the capabilities of individual robots and teamwork became increasingly sophisticated and effective over the years, with the ability to dribble, to flat or chip kick, to perfectly navigate collision free at high speeds in a space crowded with opponents as dynamic obstacles, and to coordinate the team with effective defense, accurate passes, and precise aim at narrow openings of the goals.  [VIDEO 387](#) shows an example of the multi robot teamwork by the [CMU Dragons](#).

The ongoing research directions aim at learning the opponent strategy and responding to it. Through the common vision systems, all games are logged and now available for researchers to challenge learning algorithms with the complex positional, fast game data. Furthermore, the league aims at playing games of eleven players on a much larger field, also in ad-hoc teams, where the players are elements of different and previously unknown research teams.

Middle Size

The RoboCup middle-size league ([MSL](#)) started in the first RoboCup event in 1997. The league is set on a much larger field than the [SSL](#) one, initially of the size of 3 by three ping-pong tables. Currently, two [MSL](#) teams of six wheeled robots play on a 18 m × 12 m green carpeted field, with an official FIFA winter ball (orange).

[MSL](#) clearly differs from the [SSL](#) in its lack of centralized overhead perception and offboard computation. Each [MSL](#) robot is onboard fully autonomous, equipped with onboard sensors, computation, and actuation. Through wireless communication the robots can establish interteam cooperation and receive all referee commands. These two [SSL](#) and [MSL](#) leagues, were designed to offer frameworks for different robotics research interests in perception, planning, and mechanical robot design.

The [MSL](#) robots have evolved from a variety of initial experimental designs to the very effective, fast omnidirectional robots with creative kicking and defending actuation devices, in particular also in the goalie robots. At some point, robots had omnidirectional cameras that allowed each robot to compute the position of all the players on the field, for avoiding obstacles in its motion planning. Wireless communica-

tion allows for sharing state information and supports the implementation of cooperation strategies. Currently, teamwork accomplishments are based on the effective selection of robots to roles and attacking passes. In particular, the recent rules of the game force the robot to pass the ball in the opponents middle field before shooting to the goal. In this way, cooperation and passes have become a key feature for a successful team. The [MSL](#) goalie robots have been of special note, as teams build special hardware for them to allow for kicking and to effectively defend the long and well-aimed shots from the attackers. The [MSL](#) is compelling for the largest field size in RoboCup and robots of dimensions and speed that also allow humans to test play with the robots. Since RoboCup 2007, a team of volunteer members of the RoboCup Board of Trustees always plays a game against and with the [MSL](#) winning team. Such demonstrations are well appreciated by the competition audience and participants and provide evidence to the progress of the performances of the robots.

Standard Platform

The standard platform league started with the goal of providing a common hardware platform, so that the teams can focus their development on the algorithms and compare the performance of their solutions on the same hardware. Thus, in the standard platform league, all teams use identical robots, which happened to be legged robots. In the standard platform league all the challenges of the middle-size league are present (i.e., the robots operate onboard fully autonomously), but on a platform that requires a sophisticated motion control. The motion of the robot also affects perception and causes a greater uncertainty in the estimation of the environment and, thus, in basic capabilities such as ball tracking and localization of the robot in the field. The field evolved over the years: it is currently 6 m × 9 m and the game is played by two teams of five players with an orange ball.

The league started with the Sony AIBO (Fig. 66.3), in its early stages of development in 1998. After the first year demonstration, the league attracted several researchers, and underwent a substantial development both in terms of the platform, that evolved in three major revisions after the initial prototype, and in terms of the rules and requirements for the field. The AIBO robots had a very high number of actuators (16–18) to support 4-legged locomotion and body pose. At each revision, robustness of mechanical design, sensors, and computational power, steadily improved, thus, allowing to increase the size of the field (from 3 m × 4 m, to 4 m × 6 m) and to remove artificial landmarks, side barriers and strict requirements on the lighting.

Fig. 66.3a,b Standard platform league: (a) AIBOs and (b) NAOs

Both the extremely advanced features of the platform and the availability of software developed by the RoboCup teams made the AIBO a very popular platform in research laboratories to test the performance of new legged locomotion techniques, perception localization and teamwork. As the performance of the robots improved over the years, not only the rules have evolved to meet new technical and scientific challenges, but also the games became very attractive for the general audience.

When Sony announced the discontinuation of the production of the AIBOs, RoboCup issued a Call for Platform that ended up with the choice of the current standard platform: the humanoid NAO by Aldebaran Robotics (Fig. 66.3), which has been used since 2008. The set up of the field did not change substantially; however, the biped platform required not only new locomotion, but also redesign of all the basic components. Again the platform evolved over the years, with corresponding changes of the field and rules. The current version of the NAO robot is 58 cm tall humanoid robot, with 25 degrees of freedom. The processing is provided by an Intel ATOM 1.6 GHz CPU (located in the head) that runs a Linux kernel and supports Aldebaran's proprietary middleware (NAOqi) and a second CPU (located in the torso). The platform is equipped with various communication devices, including voice synthesizer, LED lights, and two speakers, two cameras (one pointing toward the feet to control the kicking), tactile sensors and sonar rangefinders, Ethernet and Wi-Fi. The capabilities of the current platform allowed to enlarge the field to the current size (to $6\text{ m} \times 9\text{ m}$) and to remove from it all artificial features. Each game is played by five robots, plus an additional coaching robot outside the field. A section of the competition has recently started, where teams are formed by robots that are designed by different participants.

The adoption of a common platform has several advantages. First of all, the hardware is chosen so that the teams have a powerful, yet affordable robot, and speed up the development by sharing the same infrastructure.

Moreover, a standard hardware platform system makes a systematic comparison of different technical solutions more accurate. Finally, a common platform supports significantly community development that allows to reach the critical mass needed to develop complex robotic systems.

Humanoid

In the humanoid league, autonomous robots with a human-like body plan and human-like body senses play soccer against each other. The robots are designed and built by the competing teams, and include some of the best autonomous humanoid robots in the world.

The humanoid league was established in RoboCup 2002, Fukuoka. The later start, as compared with the other leagues is connected with the development of humanoid robots. The first demonstration of the early humanoid robots took place in RoboCup 2000 and Honda ASIMO first showed the ability to kick the ball, as a demonstration, in RoboCup 2002. Since then, the league started, initially addressing basic skills such as walking and kicking: the soccer game was limited to penalty kicks. In the first years of the league, very different robots were competing, but soon a separation in subleagues was gradually introduced, based on the size of the robots and on the constraints on the structure of the robot aiming to enforce dynamic walking. In 2005 the first two against two games were started in the smallest robot subleague. Since 2008, the game had three players in the kid-size and the league made a significant progress in terms of the number of participating teams and the capability of the hardware platforms. In the current setting, the robots of the humanoid league are divided into three size classes (Fig. 66.4): Kid-Size (30–60 cm height), TeenSize (90–120 cm), and AdultSize (130 cm and taller). In the KidSize soccer competition, teams have three players, in the TeenSize two players (keeper and forward) and in AdultSize soccer, a striker robot plays against a goal keeper robot in a dribble and kick competition. The size of the field is $4\text{ m} \times 6\text{ m}$ and the ball is of different size for

Fig.66.4a–c Humanoid Robots: (a) KidSize, (b) TeenSize, (c) AdultSize

the different subleagues. Unlike humanoid robots outside the Humanoid League, the task of perception and world modeling is not simplified by using nonhuman-like range sensors.

The challenges addressed by the Humanoid League embrace those arising in the realization of fully autonomous humanoid robots in the standard platform league; however, the overall design, including the hardware, makes it possible to aim at a richer range of solutions. More specifically, key issues addressed in the Humanoid League include dynamic walking, running, kicking the ball while maintaining balance, visual perception of the ball, other players, and the field, self-localization, and team play.

Conclusion

RoboCup is recognized as a major forum for research and education through competitions. The main international yearly event gathers about 200 teams, 1500 participants (not including Junior), and tens of thousands visitors. Regional events are also held worldwide, some of them of a size comparable to that of the main one. RoboCup is not only soccer, since it aims at fostering the development of new solutions also in applications that have a direct impact in our society: RoboCup Rescue, where robots compete to search and rescue in disaster scenarios, RoboCup@Home, where robots perform tasks that help people in daily life, Logistic League and the RoboCup@Work, where robots operate in industrial settings. Moreover, RoboCup provides a link to young generations through RoboCup Junior, a set of competitions specifically designed for the introduction of children to robotics and organized within the major event.

RoboCup has a profound impact on research. Researchers enter RoboCup competitions to validate their newly designed approaches to the broad spectrum of problems that arise from the grand goal of building teams of autonomous robots. Algorithms and robots are put to test in adversarial environments not previously seen, to show effective performance and ad-

vance the scientific and engineering state of the art in Robotics. There is a countless number of publications that present, in the most qualified Artificial Intelligence and Robotics venues, scientific contributions arising from the technical challenges tackled in RoboCup and validated through RoboCup games and platforms. The approaches and solutions developed in RoboCup have impacted many research areas. Particularly significant examples are the fields of humanoid robotics, multi-agents and multirobots, and performance metrics for Robotics.

RoboCup has brought significant contributions in education. The students, who form the teams, are the driving force of the effort to design and implement the components of rather complex integrated systems. Learning about cutting-edge solutions and experimenting them is a very effective way to develop creativity and design skills. Moreover, engineering within a team, in the framework of a competition, is a unique experience that goes far beyond the standard practice of academic curricula. In addition, RoboCup organized several Summer Schools, with a substantial hands-on component that has also been subsequently adopted in many other events. While some of the above features are not unique to RoboCup, the blending of ingredients and the environment provided by RoboCup have proven extremely rich, attractive and successful.

A few examples of particularly significant impacts that RoboCup had within our society are hinted below. Aldebaran Robotics NAO robot won RoboCup 2007 Open Call for a standard platform and afterward it has become popular through the standard platform league. Today NAO is deployed worldwide by research laboratories in robotics, becoming a commercial success. Kiva Systems are revolutionizing automation by using hundreds of mobile robots for storing, moving, and sorting inventory. In March 2012, Kiva Systems was acquired by Amazon. RoboCup and robot soccer were credited by Kiva's CEO for the success of the company. The search and rescue robot Quince, during the rescue oper-

ations in the Fukushima–Daiichi Nuclear Power Plant, could go up to the second to fifth floors in the nuclear reactor buildings. The robot was designed and evalu-

ated through RoboCup Rescue competitions, showing excellent mobility in comparison with the other competing robots.

66.4 Task-Oriented Competitions

In this section, we consider competitions that take their inspiration from common, but important tasks, currently undertaken by people. Competitions in this class tend to be focussed of dirty, dangerous and dull activities. Robotics of this kind is known as *Field Robotics* with robots typically having to operate in unstructured or semistructured environments, which often change over time.

The robots in these competitions are normally vehicles, such as ground vehicles (often cars), submersibles, or unmanned aerial vehicles. There is even a current high-profile competition to send a robot to the Moon, the Google Lunar X-Prize.

Unlike the competitions inspired by humans, task-oriented competitions are not driven by spectator experience. Spectators are welcomed at some of the competition events but not at all. Some are closed to competitors, organizers, and media only.

Task oriented competitions are held to drive innovation, raise the profile of a particular area of robotics, or to overcome nontechnical hurdles such as regulation and insurance which would otherwise stifle individual research projects. A competition is a more efficient method of addressing these issues than a collection of disparate research projects across the world. This type of competition also attracts professionals in robotics or soon-to-be professionals such as university students. They are hence a useful way to increase interest in industry participation and you will see major corporations with interests in the relevant technology and applications areas supporting or sponsoring a competition.

Unlike robot competitions inspired by sporting contests, task oriented competitions often happen as one-off events.

Task-based competitions in which the exact manner by which the task is to be accomplished is unknown, or significantly beyond the state of field, are often referred to as a *Challenge*. Challenges often have large cash prizes for the team that accomplishes the task reflecting the substantial investment of effort envisaged to claim the prize by the prize authority.

Ultimately even substantial cash prizes are almost always surpassed by the accumulated cost of the winning team's labour, equipment, donations by sponsors and overheads. Instead most participants are driven by prestige of conquering the challenge, *doing the im-*

possible and claiming the prize, or at least attempting to.

In recent years, the success of the robot competition format has lead to a number of contests including the MAGIC Competition [66.35], RoboCup Rescue [66.36], ELROB [66.37], and the AUVSI competitions [66.38].

A push to robot competitions to task-oriented robot challenges has also been given within the framework of scientific conferences such as AAAI and ICRA. Within this context, service robotics has also been a source of inspiration, addressing tasks such as serving drinks or preparing sushi. RoboCup@Home combines multiple challenges facing service robotics into a structured competition framework [66.39].

In the following sections, we examine at two representative task oriented competitions, the UAV challenge and the DARPA Challenge. While the robots differ significantly the drivers and approach to competition has many parallels.

66.4.1 Case Study: The UAV Challenge

Flying Robot Competitions

Competitions that encourage students to develop their skills with flying robots in exciting and challenging ways have been developed by universities and other research and education organizations since the early 1990s. One of the first, longest running and most successful flying robotics competitions is the International Aerial Robotics Competition (*IARC*) [66.40]. It was first held in 1991 at Georgia Institute of Technology. The aim of the competition is to push forward the state of the art in autonomy in flying robots. Teams are given challenges based on real-world scenarios, typically mock ups of disaster response or covert military style operations. A new challenge is announced once the current scenario is completed. Many scenarios take a number of years to be successfully demonstrated. Since 1991, *IARC* has seen six different competition scenarios. Nearly all of the scenarios involve interaction with ground elements meaning that the aerial robot must avoid obstacles and pick something up. This means that the successful platforms of *IARC* are nearly always rotary wing vehicles such as helicopters, ducted fan VTOL vehicles or in more recent year, multiro-

tor platforms. [IARC](#) is open to university-based teams from around the world. The past three [IARC](#) missions have involved the aerial robots having to navigate inside buildings as well as free-flying outdoors.

Another long running event is the International Micro Air Vehicles ([IMAV](#)) competition, which has been running since 1997 [66.41]. This competition focusses on very small unmanned aircraft operating either indoors, or in outdoor areas around an airfield or built environment. The [IMAV](#) events consist of a number of subevents, each aiming to push technology to solve specific research challenges, such as autonomy, perception, and flight dynamics. As reported in [66.41], the level of autonomy demanded to complete events has been increasing in recent years.

The Singapore Amazing Flying Machine Competition ([SAFMC](#)) is organized by Singapore's DSO National Laboratories and Science Centre Singapore and was first run in 2009 [66.42, 43]. It is typical of the type of competition event that is comprised of a number of different categories, from a basic radio-controlled flying competition to a category encouraging university level teams to design and build automated aircraft to navigate complex indoor obstacle course.

The UAV Challenge Outback Rescue is an international flying robot challenge that was first run in 2007 [66.44]. It is different to other competitions in that the aircraft have to be flown a considerable distance from the take-off and landing location. The competition revolves around a simulated scenario of a lost walker in the Australian outback with the start of the search area being 4 km from the take-off location and the furthest point of the search area being 6.5 km away. These distances require autonomous operation of the aircraft and reliable communications back to the ground stations – all things that stretch the capability of university and amateur teams [66.45, 46].

In 2013, the Wildlife Conservation UAV Challenge was launched [66.47]. This competition has a similar format to that of the UAV Challenge Outback Rescue, but is focussed on a scenario to find poachers of endangered animals in Africa. The aim of this challenge is to drive the cost down, and the reliability up, of small robot aircraft. The scoring system hence rewards teams heavily for low-cost designs, long duration capability and autonomy.

There are numerous other flying robot competitions run each year, including the USA-European micro UAV flight competition [66.48], the AUVSI Seafarer Annual Student UAS Competition [66.49], the International Universities MINI UAV Competition [66.50], the Chinese Robotics Competition which has a flying robot category [66.51], and the Annual Search and Rescue Cyber Physical Systems Challenge, where

teams build ground vehicles and the organizers provide a video feed from a UAV hovering above the indoor search area [66.52, 53]. A final category of flying robot competitions are the type held solely for participation within single universities and which are typically part of core course work in robotics or extension course work. A representative example of this type of internal university competition is given by *Schochmann* [66.54].

Motivation for Flying Robot Competitions

The stated aim of the longest running flying robot contest, International Aerial Robotics Competition, is to drive innovation [66.40], particularly in the area of autonomy. Many of the flying robot competitions and challenges of the past decades have focussed on this technology development or innovated uses of existing technology. However, not all flying robotics competitions and challenges are created for this reason alone, with some being linked to the education of high-school or university students who are studying robotics, while others are conceived to overcome nontechnologically based problems. There are a number of key issues that are potential inhibitors to the adoption of flying robots in the civilian context. In the mid-2000s, the general public considered flying robots as a military-only tool, being expensive and dangerous. This was largely due to a number of popular movies at the time depicting such things and high media interest in the use of unmanned aircraft by the USA in the Middle East conflicts of the time. In the 2010s, the public was concerned with privacy issues surrounding the use of drones (as they have become known in the media) and the fear that small unmanned aircraft could be misused by criminals or terrorists [66.55].

A second significant issue is that of airspace regulation. Flying robots will share the sky with manned aircraft. The airspace inhabited by manned aviation is highly regulated across the world. Before flying robots can be routinely used for civilian missions, both the airspace regulator of a particular country, and the general public in that country must be comfortable that flying robots will be as safe as current conventionally piloted aircraft. This issue is the single most significant hurdle to the adoption of unmanned aircraft in civilian airspace. A third issue, strongly related to the regulation and safety issue, revolves around the appropriate training, certification, and insurance of unmanned aircraft. Insurance companies work on precedence and past accident rates in order to determine risk and hence set insurance premiums. In a new industry, such as that of unmanned aircraft, with little data on which to base risk probabilities it is difficult for insurers to cover operators. Finally, as the unmanned aircraft industry grows, it will need people with the correct skills. These new

Fig. 66.5 (a) The aim of the Search and Rescue Challenge is to locate and drop a water bottle to a walker, Outback Joe. The mannequin wears bright clothes to help the teams find him using computer vision. (b) The course showing the Mission Boundary (yellow) and the Search Area (green). The airfield is at the top of the picture

Engineers, operators, technicians, and researchers will need to be trained in unmanned aircraft-specific areas of expertise.

The UAV Challenge Outback Rescue competition was created in Australia in 2007 [66.44] to attempt to simultaneously address all these major inhibitors to civilian use of flying robots. These broad aims meant that the targeted participants were from a wide cross-section of the community and included, the general public, high-school students, university students, radio-controlled aircraft hobbyists, the Australian aviation regulator (CASA), government, research institutes and universities, aerospace industry, and media.

Competition Formats and Challenges

The majority of flying robot competitions and challenges consist of multiple subevents or competitions, usually aimed at either different age groups of competitors or different skill levels. The level of complexity and the difficulty of the specific tasks set are set so that younger, less experienced students will almost always succeed to some degree and are hence competing against others like a sporting event. On the other hand, the events aimed at older or more experienced entrants are often deliberately conceived to be impossible to complete the first year that a team attempts it. These events are often referred to as Challenges while the easier events, where a team is expected to finish, are known as Competitions. A case in point is the UAV Challenge Outback Rescue that comprises a difficult Challenge, that is open to teams from around the world, and a high-school competition, that is far simpler, but still challenging, for high-school aged students. The two events share a common theme to encourage the high-school students to consider progressing to the Challenge in later years. The scenario for the UAV Challenge is that of locating a lost walker and dropping him a water bottle. Such a scenario is appealing to the general public, the media and the government.

The UAV Challenge Outback Rescue's major event is known as the Search and Rescue Challenge and was

unique in the world at the time it began in 2007 in that the competition took place over a large area of farmland and public roads. The lost walker was represented by a mannequin and was placed in a farmer's field approximately 4–6.5 km from a public airport in the regional town of Kingaroy in Queensland, Australia. The aim of the Search and Rescue Challenge was for a team to use their flying robot to find the lost walker (Fig. 66.5) and then drop him a water bottle. If a team managed those tasks, returned their aircraft safely to the airport and the water bottle landed intact less than 100 m from the bushwalker, they would win \$50 000. The Search and Rescue scenario was created to be as realistic as possible with competitors given a briefing document at the start of the day outlining where the lost walker was last seen and what he was wearing. Teams were under time pressure and given time limits on setup, mission time and pack up time. All of these restrictions were designed to make the scenario as close to a real rescue as it could be. Teams were evaluated on their mission performance and on their documentation meaning that even if no team completed the mission, their could still be a points winner, who would be awarded the title of First Place and receive a smaller cash prize. This is typical of Challenge-type events where a number of years may go by without a team completing the main challenge. Another typical feature of this event it is that it is not set up as a spectator event because the nature of the Challenge makes it almost impossible to follow if you are not directly involved in the action.

The high-school competition of the UAV Challenge Outback Rescue is known as the Airborne Delivery Challenge as takes place on the airport site and within the airport boundary. This competition is therefore set up to be a spectator friendly event. This scenario required high-school students to pilot their unmanned aircraft over the same walker, who is located in sight of the general public close to the air-side fence. Teams are required to drop a package to the walker, but the pilot cannot select when to make the drop. Instead, a second team member located in a tent and with no line of sight

Fig. 66.6 The Airborne Delivery Challenge course showing the hurdles and the flying zone

to the bushwalker has to make the drop (Fig. 66.6). The aim of this scenario is to force teams to use some technology to help assess when to drop the package. Many teams are successful and a points system determines the winner.

Qualification and Precompetition Testing

Some flying robot competitions and challenges have a qualification element to them which means that teams must demonstrate a certain level of competence prior to the actual event. This requirement implies that many of these competitions can be considered to be much longer in duration than the relatively short events that take place on the competition days at the end. The UAV Challenge Outback Rescue for example, takes place over a long time period leading up to the event. Since 2007, the Search and Rescue Challenge has been held both over a single year and as a 2-year long campaign. In both forms of the event, the high-school and the international open event, teams must provide documentation to the organizers to demonstrate their competence, their progress, and their treatment of safety. Safety is the priority issue for the organizers and the teams at flying robot competitions and challenges. In the case of true UAV Challenge, the unmanned aircraft are operated over farmland, over public roads and close to the general public who come to spectate (Fig. 66.5).

Teams first register for the UAV Challenge and are then asked to provide documentation, known as Deliverables. The first deliverable must show a basic system design and an analysis of risk. The second deliverable must show the final design and adherence to the mandatory safety features of the UAV system. For the 2-year long version of the Search and Rescue Challenge, a third deliverable was added where teams were asked to show documented evidence of at least 5 h of autonomous flight of their unmanned aircraft. This final set of documentation was introduced

to ensure that only teams that were capable of actually flying for a sustained period of time in the search range qualified for the event. By its nature, the qualification process significantly reduces the size of the field as a competition or challenge progresses. For example, in 2011–2012, 68 teams registered to take part in the Search and Rescue Challenge, with 61 submitting a the first deliverable document. Of those, 53 teams from ten countries, qualified to continue. At the second deliverable stage, 23 teams qualified to continue to the final deliverable phase where nine teams qualified and were invited to the actual flying event. Between that announcement and the event, four of the nine teams pulled out due to crashes during testing and other issues leaving just five teams to compete during the event (Fig. 66.7,66.8).

Fig. 66.7 The number of teams declines as the UAV Challenge progresses. In 2011–2012, 68 teams registered and throughout the 18 months of the competition teams dropped away leaving only 5 at the event

Fig.66.8a,b (a) First place team from the 2012 Search and Rescue Challenge, Canberra UAV. (b) Winners of the 2012 Airborne Delivery Challenge, MUROC Hawks

It is common at flying robot events to test teams prior to the actual competition flights. In the UAV Challenge Search and Rescue event, the final phase of qualification involves the teams being tested or scrutineered. The scrutineering process aims to test both the safety systems of the unmanned aircraft, the supporting systems and the team themselves, including any safety pilots. The scrutineering is undertaken by industry professionals and consists of a static scrutineering test where the team is interviewed, the aircraft and systems inspected and the flight termination tested. Teams that pass scrutineering are then invited to fly their aircraft within the boundary of the airport where the ability of the team to fly autonomous is tested. Only teams that pass this final hurdle are invited to launch a search and rescue mission and compete for the grand prize. In 2011–2012 Search and Rescue Challenge, four teams passed the final scrutineering tests meaning that just over 5% of teams that originally registered qualified for the final mission. In comparison in the 2013–2014 event, this qualification rate increased to 17%.

Regulations and Safety

Many flying robot competitions are carried out indoors. As well as guaranteeing that bad weather will not cause problems for the event, a major reason to hold a competition indoors is that in most countries, this means that the official airspace regulator does not need to be involved in any way. Unmanned aircraft flown indoors pose no threat to manned aviation flying above. However, a number of high-profile flying robot competitions do take place outdoors, including IARC and the UAV Challenge Outback Rescue. The latter event must be undertaken within the specific regulations for the operation of unmanned aircraft in Australia. These regulations were launched in 2002 by Australia's civilian air regulator, the Civil Aviation Safety Authority (CASA) and are known as CASR Part 101. The reg-

ulations outline the operating rules for three defined classes of unmanned aircraft, micro UAS under 100 g, small UAS 100 g to 150 kg and large UAS 150 kg and above. The rules of the UAV Challenge dictate that the competing team's cannot enter an aircraft in the large UAS class. Normal commercial operation of small UAS would require the operating business to obtain an Operators Certificate from CASA. However, the competition is classified Sport and Recreation by CASA and hence an Operator Certificate is not required. CASA treats the UAV Challenge organizers as the body accountable for the safe conduct of the event and adherence to the relevant regulations. The UAV Challenge organizers have developed the event rules to specifically meet the requirements of the regulations and to hence ensure that if a team is following the rules, they are in turn not in breach of the regulations. Further to this, the organizers have also developed a detailed Policy and Procedures manual that outlines how the UAV Challenge will be conducted to ensure safety and adherence to the regulations by the organizers themselves. Developing the manual and the supporting rules has been a major activity of the organizing committees over the years that the event has been run and is a significant output from the whole UAV Challenge activity.

What makes the UAV Challenge different to many other unmanned aircraft competitions is that because the event takes place largely beyond visual range of the team's ground controllers, and an aircraft could be up to 7 km from the ground station, there is a higher potential for a so-called fly-away than there is during the more common style of events where the flying takes place in close proximity to the ground station. A fly-away is where the aircraft flies out of the designated competition area and cannot be commanded to return. Such an incident could be seen as a major setback to the developing unmanned aircraft industry. In the first 2 years of the UAV Challenge, the mitigation for fly-away was to mandate the use of a flight

Fig.66.9a,b DARPA grand challenge vehicle ancestry. Pioneering autonomous vehicles of 1980s, 1990s. (a) 1985: UBM's Vamors. (b) 1995: CMU's Navlab 5 used for the *No Hands Across America* trial

termination mode whereby any aircraft that crossed the defined competition boundary or lost contact with the ground station had to automatically perform a fast dive into the ground. All aircrafts were tested during the scrutineering sessions to ensure that this behavior was built into the systems. Since, 2010, the requirements have kept step with the more common industry approach to lost communications and teams are now allowed to deploy aircraft that will automatically return to a predetermined location in the competition area should communications be lost between the ground station and the aircraft. The requirement to automatically terminate a flight on competition boundary crossing remains and is still the last line of defence against a fly away. Many teams have lost aircraft during the testing and development of their flight termination systems and this requirement is still one of the most challenging of the UAV Challenge.

Organization and Sponsorship

The nature of flying robot competitions and challenges often require large teams of organizers with complementary skills. For example, the UAV Challenge Outback Rescue is organized and run by two committees whose members typically come from the organizations that provide support for the event. The first committee is the Steering Committee and runs all nontechnical aspects of the UAV Challenge event such as equipment hire, securing sponsorship, liaising with local government and carrying out event communications and media activities. This committee is also responsible for the event finances. The second committee is the Technical Committee. This committee is responsible for developing and releasing the rules for the UAV Challenge. The committee also liaises with air regulator and works with the UAV Challenge Steering Committee on the event organization. At the event, the Technical Committee is responsible for the airside part of the UAV Challenge which includes selection of the technical team that runs all technical issues relating to the event, scrutineering of the teams, the supervision and scheduling of the actual competition flights and the coordination of aerodrome activities during the event times. The Technical Committee meets regularly throughout the year with initial meetings held to formulate the

rules and incorporate lessons learned from the previous year. The Technical Committee reports to the Steering Committee.

Each time the UAV Challenge is run, sponsors are sought to cover the costs of the prize money and the hire of facilities. The organizations that come together to run the UAV Challenge provide the time of their staff as an in-kind contribution. The total budget of a UAV Challenge is approximately \$125 000 plus the staff time of the organizers. It is hence a considerable undertaking and requires a significant number of sponsors to break even. The UAV Challenge has been well supported over the years, attracting the sponsorship of major aviation companies such as Boeing and Lockheed Martin as well as unmanned aircraft companies such as Insitu. The safety regulator, **CASA**, has also sponsored the event.

66.4.2 Case Study: The DARPA Challenges

In 2001, the United States Congress challenged the Department of Defence with the following mandate [66.56]:

It shall be a goal of the Armed Forces to achieve the fielding of unmanned, remotely controlled technology such that by 2015, one-third of the operational ground combat vehicles of the Armed Forces are unmanned.

In response, a little over a year later, the Defense Advanced Research Projects Agency (**DARPA**), the primary research and development organization for the United States Department of Defense, announced that there would be a race.

The race, to be titled the **DARPA** grand challenge was to drive a robot car 300 miles from Los Angeles to Las Vegas in the fastest time to claim the \$1-million dollar prize [66.57].

The aim of the **DARPA** grand challenge was to reinvigorate and extend autonomous vehicle technologies from the 1980s and 1990s to future defense vehicles. Initiatives such as the Universität der Bundeswehr Munich (**UBM**)'s Vamp/Vamors vehicles, University of Parma and Carnegie Mellon University's NavLab's research program (shown in Fig. 66.9) had demonstrated

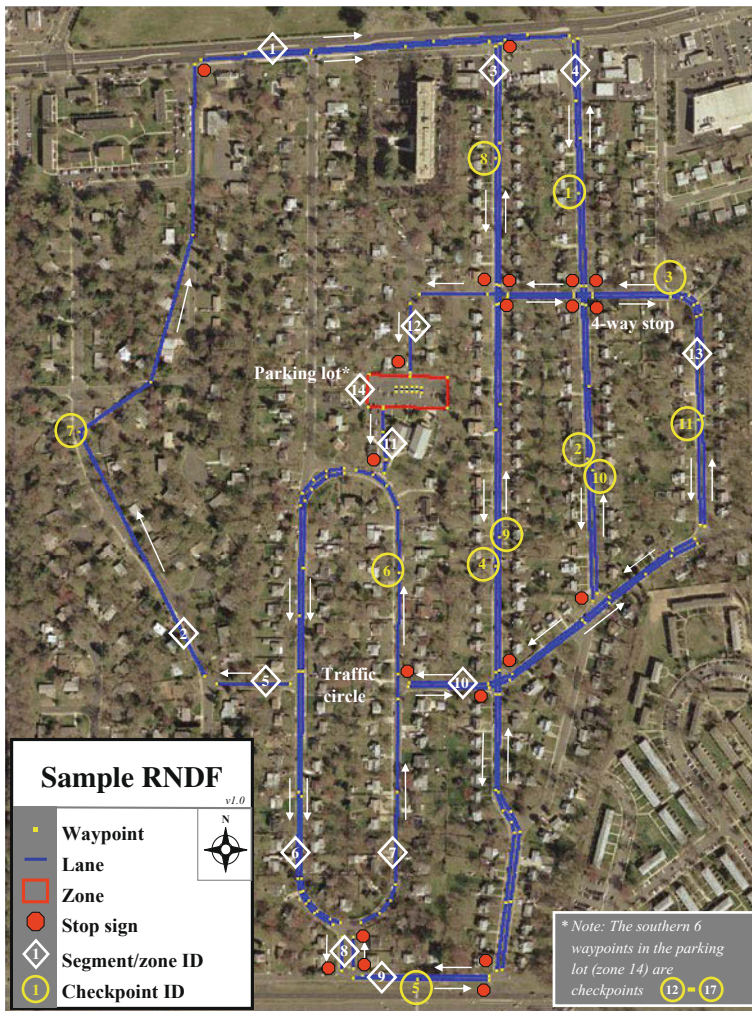

Fig. 66.10 A sample route network definition file (RNDF) provided by DARPA for the 2007 Challenge (overlaid on aerial imagery)

impressive feats of road vehicle autonomy. Trials across thousands of highway kilometres had demonstrated lane keeping, obstacle avoidance and even automatic overtaking (passing) [66.58–60].

The problem was, close to a decade later, the capability of current technology full-sized, fully autonomous vehicles was unknown. The impressive trials of the late 1980s and 1990s concentrated on highway driving where the primary task was computer vision-based lane keeping. There were indoor and outdoor robots navigating through challenging *obstacle field* style environments [66.61, 62]. There were also teleoperated vehicles already in use by the defense forces. The question was, given computation power tracking with Moore's law over the intervening years and many other advances (such as the use of LIDAR), what would robot car be capable of?

DARPA aimed to [66.63]:

- *Demonstrate an autonomous vehicle able to travel over rugged terrain at militarily relevant speeds and distances.*
- *Accelerate autonomous ground vehicle technology development in the areas of sensors, navigation, control algorithms, hardware systems, and systems integration.*
- *Attract and energize a wide community of participants not previously associated with Department of Defense programs or projects to bring fresh insights to the autonomous vehicle problem.*

Potential participants were drawn to the challenge. Many participants could also see the potential for related technologies in the automotive industry and for road safety [66.64].

Teams would develop a vehicle that could follow a simple route across a course representing typical ter-

rain encountered by defense vehicles. The route map would be a set of paths specified by GPS way-points. The vehicle would be then given a list of destinations in the map and instructed to drive to each location. A typical route map is shown in Fig. 66.10 overlaid on the satellite image.

For this first competition, as for those that followed, the rules stated that the robot must be a fully autonomous and unmanned ground vehicle. Each vehicle was fitted with a wireless remote E-stop to bring the vehicle to a halt. On the base vehicle was added sensing, processing, and control. Some vehicles were built from the ground up. Most teams fit actuators to the manual controls of an existing vehicle, some built upon disability aid kits fitted to the vehicle. A couple teams were able to tie into existing *by-wire* capabilities of the vehicle, a notable example being Victor Tango's 2007 challenge entry *Odin* [66.65]. In addition to GPS, vehicles needed to have sensing for obstacle avoidance, in which LIDAR sensors dominated. As the vehicles were to be completely autonomous, all sensor processing, and control had to be done on-board so a certain amount of computer power was incorporated. Then the practicalities would necessitate other devices such as power generators and additional air conditioning, if required. The general anatomy of a DARPA grand challenge vehicle is illustrated at Fig. 66.11. This vehicle, from the 2007 DARPA Urban Challenge, was at the upper end of the spectrum for additional equipment with LIDAR, video cameras and automotive radar, as well as a generator and supplementary air conditioning required for a blade server computer housed in the rear compartment [66.66].

2004 DARPA Grand Challenge

DARPA hired *Score international*, an off-road race organizer, to develop the course [66.67]. A 142-mile course was laid out through the Mojave Desert. The competition was structured as a time trial to complete the course in the shortest time under 10 h. One hundred and six teams applied.

In March 2004, 25 teams turned up for the competition. In the days leading up to the race a qualifier, inspection and demonstration (QID) round was conducted. This event was primarily to verify that the vehicles were fit to compete and capable of operating safely. By race day, the 15th of March 2004, a field of 15 vehicles had qualified and were ready to race.

As stated earlier, a primary goal of the competition was to gauge the state the art in the field. Steep elevation, blind turns, and sheer drops adjacent to the course were included to challenge the vehicles. While the degree of difficulty was low by human off-road driving standards, the course was designed to be in-

teresting and make for a good competition [66.67]. Expecting something akin to human driven competition, DARPA even advised the media to set up at the finishing line where the action was expected to take place [66.68].

However, the course and the autonomous driving problem proved too difficult for the robot vehicles. No vehicle made it beyond the first seven miles of the course. After a promising start the vehicles soon became stuck or had to be disabled by a safety official after deviating from the course. One vehicle's wheel caught on fire, another flipped around a bend another began circling around in the starting chute [66.69].

Inexperience was the chief cause of failure on the 2004 contest. The new nature of the challenge and the stretch of mobile robotics to a full-sized off-road vehicle introduced too many complications for the robots systems.

The challenge stood unbeaten, the prize money remained unclaimed. The real world complications and the size of the challenge were now apparent. Also apparent, however, was the curiosity sparked within the research community and the general public.

Three months after the first competition, DARPA announced the 2005 DARPA Grand Challenge – a re-run of the event, this time for a \$2-million dollar prize.

2005 DARPA Grand Challenge

With a slightly longer lead time, DARPA held a participants' conference and conducted site visits to each team to gauge progress. At the participants' conference team representatives and DARPA officials discussed the draft race rules, clarifying rule interpretations and technical specifications. Out of 195 entrants, DARPA officials flew out to attend 118 site visits.

Fig. 66.11 Anatomy of a DARPA grand challenge vehicle. 2007 DARPA Urban Challenge entrant MIT's *Talos* was on the upper end of the additional equipment spectrum

From the site visits 43 teams were selected to participate in the national qualifying event (NQE). During the qualifying event, which was twice as long as 2004, the teams had to complete a miniature version of the course which was created at the California Speedway (Fontana, California, Fig. 66.12).

By race day, 23 robots were selected as starters in the race. The vehicles queued up to start at 5-min intervals. DARPA officials paused slow-moving vehicles to permit faster robots to pass.

The difference between the 2004 and 2005 competitions was stark. Eighteen months on from the first competition, five robots drove 132 miles across the Mojave Desert to complete the course [66.63].

The race winner *Stanley*, from the Stanford Racing team, claimed the prize – completing the course in 6 h, 53 min and 58 s (Fig. 66.13) [66.70]. Second and third places were taken by robots from Carnegie Mellon University (CMU) teams: *Red Team* and *Red Team Too* [66.63]. *Kat-5* from Team Gray came forth, a remarkable achievement from a team founded by Louisianan insurance executives. And last, but not least, the 16-ton *TerraMax* truck by the Ochkocho Truck Corporation which completed the course the following day after spending the night *paused* on the course.

Fig. 66.12 Miniature version of the course which was created at the California Speedway

Fig. 66.13 Winner of the 2005 grand challenge Stanford Racing's robot *Stanley*

It was a trail blazing event which captivated the public with news images of unoccupied race vehicles kicking up dust as they drove across the Mojave desert sand.

During the qualifiers and the race some common weaknesses were also identified. The vehicles required GPS for navigation as all the course information were given GPS coordinates, however the vehicles also appeared to be overly reliant on a strong, correct, GPS signal. During the race vehicles drove under high voltage power lines which caused GPS loss. Vehicles deviated from the course or even crashed due to loss or multipath signals. Several robots were also able to make significant progress *driving blind* after sensor failures meant that local obstacle avoidance was no longer functioning correctly.

In 2006, DARPA announced the next grand challenge, the *DARPA Urban Challenge*. The contest this time required fully autonomous vehicles to drive on an urban street network.

2007 DARPA Urban Challenge

In the *DARPA Urban Challenge*, robot vehicles were to follow the Californian driver's handbook. Unlike the previous challenge where vehicles were not intentionally presented with moving obstacles (other robots were paused when they became too close to each other) the aim of the contest was to test the vehicles' ability to drive in traffic. This time vehicles were expected to keep to lanes, queue in traffic, park, merge, pass, and even observe intersection precedence (i. e., yield to cars already at an intersection) [66.71].

In a new element in the 2007 Challenge, DARPA introduced seed funding of up to \$1-million dollars for per team for 11 teams based on a competitive application process to bootstrap the cost of development of the increasingly complex robot platform. The seed funding attracted new entrants to the competition in line with DARPA's aim to attract a wide community of participants [66.72].

On November 3, 2007, the urban challenge event (xUCE) was held in Victorville, California. This event set loose, simultaneously, for the first time, 11 full-size autonomous vehicles on a closed course (Fig. 66.14).

The UCE was held on a closed course within the decommissioned George air-force base. The course was predominantly the street network of the residential zone of the former base with several graded dirt roads added for the competition. The contest was cast as a race against time to complete three missions. The missions were different from each team but were designed to require each team to drive 60 miles to finish the race. Penalties for erroneous or dangerous behavior were also converted into time penalties.

Most roads were paved with a single lane in each direction as typical for a suburban street. A couple of roads had two lanes of traffic in each direction to simulate an arterial road or highway. One road, in the southeastern corner of the network, was a raised dirt road constructed especially for the event.

This time all 11 qualifying robots were allowed to interact in the UCE course simultaneously, with additional traffic vehicles driven by professional drivers. For the third time, like anxious parents, the researchers manned the fences helpless as the robots, whose development had consumed the past 12 months of their lives, one by one, drove away. There were some tense moments and even a fender bender [66.66, 73]. However, powering through the mission objectives with a driving style described as *a soccer mom with some place to be* [66.74], CMU's Tartan racing's robot *Boss* (Fig. 66.15), crossed the finish line [66.73] to claim the prize. 2005 winning team Stanford Racing came second with *Junior* while team Victor Tango's robot *Odin* secured third place. Six robots completed the race [66.72].

Review

DARPA endorses the use of competitions to cause paradigm shifting advances in science and technology. As stated DARPA's 2007 Fiscal year report [66.72]:

Fig. 66.14 DARPA starters

Fig. 66.15 Tartan racing's robot *Boss* crossing the finishing line

The program achieved its program goals and stimulated interest in the programs and projects of interest to the DoD Science and Technology (S&T) community. It was successful in attracting considerable joint investment by the participants and their sponsors, effectively leveraging Government investment in the program. The technical challenge was carefully defined and staged to bring coherence to the community and increase the chance for cross-fertilization among competing groups. The solicitation and qualification process was successful in attracting a large pool of strong teams with participation from the defense industry, automotive industry, academia, as well as a number of smaller organizations. This investment in expanding the community will continue to pay dividends as DoD benefits from a strengthened commercial sector autonomous vehicle technical community. The program has been successful in attracting many young people to work on S&T problems in areas affecting national security, and benefits are expected to accrue for many years as this group enters the work force.

Although DARPA's approach may raise the question of whether research initiated by the competitions should be supported beyond competition, DARPA's view is that its role is to kick start ground breaking research not bring it to completion [66.1]. They encourage research teams and commercial organizations to team up to bring the technology to market for defense vehicles [66.72].

Velodyne LIDAR, a dominant sensing technology in the 2007 grand challenge, was developed with road safety potential in mind by Team DAD from the 2005 DARPA grand challenge [66.75]. The invention is a good example of the technological pull DARPA was wanting to achieve with the competition.

Another direct outcome of the competitions is the Google self-driving car project, which is based on the research and researchers from grand challenge teams [66.76]. Many vehicle manufacturers, such as Ford, General Motors, Volkswagen, and Toyota among others, have either entered the competition, partnered with teams or employ competition alumni to continue to develop and apply related technologies to road safety [66.64, 70, 72].

The DARPA Robotics Challenge

Buoyed by the success of the grand challenges, DARPA now hopes to accelerate the development of humanoid rescue robotics. In April, 2012 DARPA proposed the DARPA robotics challenge. The Challenge is to develop an adaptable ground robot capable of completing tasks in a dangerous and degraded environments, using hand

Fig. 66.16 DARPA robotics challenge conceptual illustration

tools to driving vehicles for disaster relief operations (as illustrated in Fig. 66.16 [66.77].

Similar to the first grand challenge, an ambitious goal has been set to inspire and stretch the state of the art.

Though it is important to note that the new robotics challenge is a separate research program from the previous grand challenges, some best practices and lessons learned from the previous Challenges have been adopted. Entrants are divided into four tracks. Tracks A and D compete to develop hardware and software of a complete robotic system. Tracks B and C compete to develop software first to run on a common simulated robot. Tracks B and C will then compete in a virtual competition. In 2014, successful Track B and C teams will be able to develop and deploy the software to a common robot platform provided by DARPA. The entrants can also apply for seed funding (similar to the), which differentiates teams between Tracks A and B, who have DARPA seed funding, and C and D who are self-funded [66.77].

The idea of using a common platform across teams and a simulator-based challenge addresses the observation that successful teams in the 2007 challenge had arrived upon similar sensors and sensor configurations. So a future challenge could remove the significant hardware development burden by allowing teams to compete on a common platform. The motivation is to once again broaden field of participants [66.77].

The new robotics challenge also introduces access to a remote human supervisor. Previous challenges were strictly fully autonomous. A criticism had been that due to the extreme lack of contextual information available

to most robotic systems, simple ambiguities that arise can impede a robot unnecessarily if a supervisor can correct the problem. The lack of supervisory control meant that in previous challenges vehicles would appear *overly cautious*.

For example, many vehicles in the 2004 Challenge were incapacitated by trivial problems such as the robot misjudging which side of a road boundary they were actually on. Full autonomy should be the ultimate aim; however, allowing limited supervisory contact would have permitted the 2004 contest to continue allowing more trial time for teams.

Conclusion

DARPA never aimed to create the ultimate autonomous vehicle. The true aim of the competition was to advance the science and technology research and education underpinning the original Congressional mandate on autonomous vehicles.

Of course, the exercise has come with considerable cost. From the 2007 Fiscal report [66.72] the true dollar cost to DARPA of the competition came in at around 25 million dollars. Three and a half million dollars were paid directly to the winning teams as prize money. A further \$11 million was paid in Track A grants to teams, with the remaining \$10.5 million was used to host the participants' conference, site visits, qualifying round, and stage the final event.

Notwithstanding these costs and the necessarily limited nature of these competitions – which create an artificial environment to focus a broad group of experimenters on a common goal, for a given period of time – they have brought clear benefits for DARPA, and the field of robotics.

Regardless of the percentage of autonomous vehicles fielded by the Department of Defense in 2015, the experience shared by participants from: research institutions, car manufacturers, defense contractors, technology companies, schools, a loud speaker company [66.75] and even insurance executives [66.78] to attempt the challenge of creating a full size, fully autonomous, self-driving car has gathered the field for an even greater race. The race between companies such as Google, Mercedes Benz, Toyota and their technology suppliers to bring these vehicles to market not only for defense vehicles but for all road vehicles.

An outcome beyond the dreams of the forward thinkers in the 2001 Congress.

66.5 Conclusion and Further Reading

In this chapter, we have discussed several types of robot competitions highlighting their impact on research and education. Here we summarize the manifold impacts of competitions as well as the major issues that need to be addressed to design and run them.

Robotics competitions with ambitious aims can provide significant breakthroughs in the development of science and technology.

To this end, competition models based on one time challenges have the advantage of being able to headline a fresh new goal. The drawback for the organizer and participants is the significant effort to build systems and infrastructure that may be too specialized to be used after the competition for subsequent challenges. On the other hand, challenges that are developed across the years can benefit from a continuous development, as long as they suitably build on yearly achievements, without loss of focus on the long-term roadmaps. The two approaches as outlined in the case studies demonstrate the merit of both as well as the unquestionable impact on science and technology.

Robots are complex systems composed of many mechanical, electrical, software, and algorithmic components and as such are hard to test and compare. In isolation a test can be derived to evaluate some components or subcomponents. For example, one can test the degrees of freedom of a mechanical design, or the bandwidth and latency of a data bus. Image processing and mapping algorithm development have made great strides using shared datasets to compare results. The performance of a robot system as a whole would often fall back to a qualitative assessment presented as a video accompanied by the encouraging words of the researcher. Competitions provide the motivation and the forum for robotics researchers to undertake the significant effort (in time, compatibility, and transportation) to develop and validate innovative solutions on complex systems under controlled conditions.

Robot competitions have a positive impact on robotics research groups in that the team work requirement within and between groups means that a better standard of core software is achieved across the group. Good tools in terms of software libraries and best practice by the more experienced software engineers in a group are often adopted across the team enabling algorithms to make it onto robot hardware sooner. To this end, it is critical that competitions support the sharing of solutions and tools, by developing community infrastructure and resources. This kind of gently enforced openness keeps competitions competitive, fosters interactivity between teams and encourages diversity of participants by minimising the barriers to entry.

Robot competitions can play a tremendous role in education. They are attractive to students and teachers, while providing an interdisciplinary framework to support the development of several types of technical skills, including teamwork. Maintaining a good balance between competing and learning becomes a major concern when the focus of the competition is education. In international competitions with younger students, differences in culture and language need to be carefully taken into consideration to maintain fairness and inclusiveness.

Last, but not least, robot competitions have a significant impact on public opinion and the public understanding of the science and technology. Simple distinctions such as autonomous versus teleoperated robotics are often mistaken or overlooked by the news media and the public. Human-inspired competitions have attracted many spectators and the attention of the media, and they certainly contribute to make scientific progress more accessible, through the language of sports. Grand challenges, such as the [DARPA Challenges](#) have been extensively covered by the media, thus, contributing, although from a different perspective to disseminate the awareness on the progress of robotics in the society.

The aforementioned outcomes do not come without a significant effort. A successful competition must clearly define a target participation and suitably support it, by making the entry level accessible to a large number of participants. The technical challenge needs to be appropriately compelling and attractive; moreover, the competition setting must ensure that winning is achieved through innovation and scientific progress. This is achieved by designing the requirements on the robots and on the competition scenario as well as through a well-designed performance assessment.

The organization of competitions also comes with formidable challenges: logistics for transporting robots and teams, venue and infrastructure for the competition event, safety of participants and spectators. The financing and administration, often underestimated, also requires substantial preplanning, know-how, and resources.

This notwithstanding, we expect the use of competitions to motivate, educate, and foster research innovation only to increase in coming years as competition has proven to be a particularly useful tool for robotics research.

66.5.1 Further Reading

Research results of robot competitions are often accumulated into a journal special issue. The reader is

encouraged to explore the articles as they are often approachable and can include interesting details of events during the contests. For the DARPA grand challenge the reader may refer to the *Journal of Field Robotics* Volume 23 (2006) Issues 8 and 9 or the *Springer Tracts in Advanced Robotics* Volume 36. For the DARPA the reader may refer to the *Journal of Field Robotics* Vol-

ume 25 (2008) Issues 8 and 9 or the *Springer Tracts in Advanced Robotics* Volume 56. In future, similar special issues are likely to be available on the DARPA robotics challenge.

US Innovation Programs [66.79] is interesting review on the broader discussion of competitions in funding science and technology research.

80 Roboethics: Social and Ethical Implications

Gianmarco Veruggio, Genoa, Italy
 Fiorella Operto, Genoa, Italy
 George Bekey, Arroyo Grande, USA

Robots and Humans covers some of the most recent advances concerned with human–robot interaction, ranging from designing biologically inspired robots, to programming and safety issues for human–robot interaction, and ethical issue brought forth by robotics. Our field’s future vision for technology is the leap from personal computers to personal robots, in a world where robots exist pervasively and work side by side with humans. Over the past 50 years we have made great strides in robotics, as the previous parts of this Handbook show. However, there are still new capabilities that need to be developed and existing capabilities that need to be improved to create a world in which robots and humans work together. Robot bodies should be easily integrated into our living environments. Robots should be safe to be around. Robots should take commands from human users easily. Robots should be functionally capable. Robots should engage humans to help mitigate error states and task uncertainties. Meeting these challenges will bring robots closer to our vision of pervasive robotics.

The topics in **Part G** are essential for creating robots that operate in human-centered environments. The chapters cover organically human-centered and life-like robots and include hardware design, control (of locomotion, manipulation, and interaction), perception, user interfaces, and social and ethical implications for robotics. As such, Part G builds on all of the Handbook’s previous parts. The connection with the chapters in Robot Foundations (Part A) and Robot Structures (Part B), particularly Mechanisms and Actuation (Chap. 4), Sensing and Estimation (Chap. 5), Motion Planning (Chap. 7), Robotics Systems Architectures and Programming (Chap. 12), AI Reasoning Methods for Robotics (Chap. 14), Robot Hands (Chap. 19), Limbed Systems (Chap. 17), Modular Robots (Chap. 22) and Wheeled Robots (Chap. 24) are essential. There is also an important dependency on Sensing and Perception (Part C), Manipulation and Interfaces (Part D), and Moving in the Environment (Part E) as these chapters cover some of the basic algorithms and technologies required by robots operating in human-centered environments.

Today’s approach to computation has progressed naturally from desktop computing, to mobile computing, to pervasive computing, ultimately leading to computation for interaction with the physical world. In other words, Part G of the Handbook on Robotics presents a snapshot of the field’s advances for creating machines in our own image that are smart and obedient. With this overview of Part G, we now provide a brief synopsis of each chapter.

Chapter 67, Humanoids, provides a concise overview of the state of the art in creating human-like machines, starting with a historical and philosophical discussion on the human example and understanding intelligence. These machines are capable of bipedal locomotion and manipulation. In addition, humanoid robots can take advantage of their entire body (e.g., lifting objects while moving the body to compensate for the load). Control issues specific to humanoids include static and dynamic stability during a mobile manipulation action. Humanoid robots interact with humans via perception systems and should be capable of interpreting behavior and mood as well as via speech systems for interpreting human language.

Chapter 68, Human Motion Reconstruction, describes the most recent algorithms that rely on data from motion capture systems to synthesize human-like motion models for machines. The chapter introduces two models for information capture: optical motion capture and mechanical motion capture. The skeleton model is computed on the captured data using kinematics and dynamics models. Musculoskeletal models can also be computed for motion analysis involving muscles. The chapter discussed model identification techniques, segmentation of human motion, classification of human motion, as well as temporal sequencing and linguistic classification of human motion. The chapter concludes with a survey of techniques for motion reconstruction for robots.

Chapter 69, Physical Human-Robot Interaction, discusses what happens when humans and robots share the same workspace and come into contact with one another. Safety can be jeopardized by mechanical failures, operator errors, or software problems. Designing and controlling robots with safety guarantees is a very important precondition for physical human–robot interaction (pHRI). The chapter discusses safety standards for pHRI and surveys several approaches to safety.

Chapter 70, Human Robot Augmentation, introduces wearable robotics systems that enhance the capabilities of the humans wearing them, while allowing the humans to control them to enhance their performance in a task-specific way. There are three types of devices that deliver human augmentation:

- i) Prostheses, for the functional replacement of human limbs
- ii) Powered orthoses, which function is to actively operate in parallel with unhealthy human joints
- iii) Robotic exoskeletons that operate in parallel with healthy human limbs.

The chapter describes prostheses, powered orthoses and exoskeletons for upper limb, lower limbs and whole body structures. State-of-the-art devices together with their functionalities and main robotics components are presented for each class of wearable system. Critical design issues and open research aspects are reported.

Chapter 71, Cognitive Human Robot Interaction, considers human(s), robot(s), and their joint actions as a cognitive system. This chapter surveys the state of the art in modeling, algorithms, and design guidelines to enable the design of systems where humans and robots can interact. The chapter describes the representations and actions that allow robots to participate in joint activities with people and the models of joint activity for human-robot interaction. The chapter also describes recent research on developing a deeper understanding of human expectations and cognitive responses to robot actions. This chapter draws on research questions and advances from a wide range of fields including computer science, cognitive science, linguistics, and robotics.

Chapter 72, Social Robotics, discusses the creation of robots designed to interact with people in a social and emotional way for applications in education, entertainment, health care, etc. These robots' embodiment is life-like and they are capable of multi-modal communication. The chapter uses a case study of the Kismet robot to illustrate the idea of a machine capable of projecting emotion. The chapter surveys some basic approaches to giving robots sociocognitive skills such as shared attention, emotional empathy, and mental perspective tasking.

Chapter 73, Socially Assistive Robotics, covers the design of human-robot systems that use verbal and non-verbal expression and communication to interact and assist users through social rather than physical interaction. Socially assistive robotics (SAR) focuses on the challenges of providing motivation, coaching, training, and rehabilitation through non-physical interaction; such systems have been validated in hands-off stroke rehabilitation, social skill training of children with autism, and eldercare, among others. This chapter reviews the critical societal issues that have motivated research into socially assistive robotics, describes the reason why physical robots rather than virtual agents are essential to this, highlights the major research issues within this area, describes the primary application domains and populations where SAR research has shown an impact, and closes with some of the ethical and safety issues.

Chapter 74, Learning from Humans, covers important topics about how we approach teaching robots

what to do by providing either good or bad examples. This is an intuitive approach to robot control and learning of tasks with the potential of opening robot applications to non-expert users. The chapter starts by discussing what it means for a robot to learn a new skill and surveys several learning approaches for this. Biologically oriented learning approaches such as conceptual models of imitation learning and neural models of imitation learning are also introduced. The chapter concludes with several open issues in robot programming by demonstration.

Chapter 75, Biologically Inspired Robots, starts with a discussion of the difference between bio-inspired and biomimetic robots. Bio-inspired robots seek to reproduce a natural phenomenon but not necessarily the underlying means. Biomimetic robots reproduce both the natural phenomenon and the means. The chapter starts with a survey of bio-inspired morphologies. A survey of bio-inspired sensors from vision to audio, touch, smell, and taste is then presented. Bio-inspired actuators include locomotion topics such as crawling, legged locomotion, climbing swimming, flying, and manipulation. The chapter also examines bio-inspiration in the context of control and planning. This includes behavior-based architectures, learning robots, evolving robots, and developing robots. Finally, the chapter examines how to make machines self-sustaining from an energy point of view.

Chapter 76, Evolutionary Robotics, discusses a method for creating robots that is inspired by the Darwinian principle of selective reproduction of the fittest captured by evolutionary algorithms. The chapter introduces the evolutionary computation method and presents several case studies. Because the evolutionary method requires intensive computation, it is often run in simulation and the final result is transferred to the robot platform. However, in the recent past there were several successes with running evolutionary algorithms in real time on physical platforms to achieve complex behaviors such as learning to walk.

Chapter 77, Neurobotics: From Vision to Action, looks at how neuroethology, the study of brain mechanisms for animal behavior, inspires the creation of a central nervous system for a machine. The chapter presents several case studies that sample this bio-inspired design of robot controllers structurally and functionally: the optic flow in bees and robots, visually guided behaviors in frogs and robots, and navigation in rats and robots. The chapter then examines the role of the cerebellum in motion control and the role of mirror systems. The chapter concludes by observing the brain has evolved to serve as action-oriented percep-

tion, which is a useful guiding principle for building robot controllers.

Chapter 78, Perceptual Robotics, discusses principles derived from high-level cognitive processing in vision in the human brain that have led to results in robotics and computer vision. The chapter is focused on the technical realization of perceptual functions in robots by examining relationships between biological perception and robotics systems. Object recognition is used as an exemplary task and issues such as representation, structural description models, neural representations, as well as recognition and learning algorithms are discussed. Next, example-based movement representations are examined to establish the connection between the functionality of the visual cortex and a class of computer vision algorithms.

Chapter 79, Robotics for Education, provides an overview of the key ingredients that make successful education robots possible. It begins with a survey of robot tournaments, which are the most prevalent mechanism for educating young students in robotics. Robot tournaments have already impacted tens of thousands of students across diverse geographic and age group boundaries. Next, the chapter technology stan-

dards required for effective use of robots in education. Educational robot devices consist of both hardware (pre-assembled or as kits or components) and software (both as source code and programming environments). The chapter surveys the physical robot platforms that have achieved notable success, and the software that enabled the interaction with young students (that is, the low-level controllers that interface those platforms to high-level computation and the top-level programming environments.) Finally, the chapter describes how conventional analytical tools may be used to evaluate unconventional educational programs that use robots.

Chapter 80, Roboethics: Social and Ethical Implications, discusses the social and ethical implications in a society where robots coexist with humans. Starting with a philosophical introspection into the dangers of unlimited use of technology, the chapter argues for the need for a new ethics of robots. Many other factors, including the cultural differences in societies ready to accept robots, define this need. The chapter surveys the code of ethics, privacy, accuracy, intellectual property, and access, which could be adopted by robotics. A taxonomy of robot types, along with socio-ethical issues for each robot type is then presented.

67. Humanoids

Paul Fitzpatrick, Kensuke Harada, Charles C. Kemp, Yoshio Matsumoto, Kazuhito Yokoi, Eiichi Yoshida

Humanoid robots selectively immitate aspects of human form and behavior. Humanoids come in a variety of shapes and sizes, from complete human-size legged robots to isolated robotic heads with human-like sensing and expression. This chapter highlights significant humanoid platforms and achievements, and discusses some of the underlying goals behind this area of robotics. Humanoids tend to require the integration of many of the methods covered in detail within other chapters of this handbook, so this chapter focuses on distinctive aspects of humanoid robotics with liberal cross-referencing.

This chapter examines what motivates researchers to pursue humanoid robotics, and provides a taste of the evolution of this field over time. It summarizes work on legged humanoid locomotion, whole-body activities, and approaches to human-robot communication. It concludes with a brief discussion of factors that may influence the future of humanoid robots.

67.1 Why Humanoids?

Throughout history, the human body and mind have inspired artists, engineers, and scientists. The field of humanoid robotics focuses on the creation of robots that are directly inspired by human capabilities (Chap. 75). These robots usually share similar kinematics to hu-

mans, as well as similar sensing and behavior. The motivations that have driven the development of humanoid robots vary widely. For example, people have developed humanoid robots to serve as general-purpose mechanical workers, entertainers, and test-beds for theories

from neuroscience and experimental psychology [67.1–3].

Notably, while this chapter focuses on robots that have been explicitly designated as humanoid robots by their creators, the lines between these robots and others can be blurry. Many robots share characteristics with humans, or have been inspired by humans.

67.1.1 The Human Example

On a daily basis, humans perform important tasks that are well beyond the capabilities of current robots. Moreover, humans are generalists with the ability to perform a wide variety of distinct tasks. Roboticians would like to create robots with comparable versatility and skill. Considering the physical and computational mechanisms that enable a person to perform a task is a common approach to automating it. Exactly what to borrow from the human example is controversial. The literal-minded approach of creating humanoid robots may not be the best way to achieve some human-like capabilities (Chap. 65). For example, dishwashing machines bear little similarity to the manual dishwashing they replace.

67.1.2 The Pleasing Mirror

Humans are humanity's favorite subject. A quick look at popular magazines, videos, and books should be enough to convince any alien observer that humanity is obsessed with itself. The nature of this obsession is not fully understood, but aspects of it have influenced the field of humanoid robotics.

Humans are social animals that generally like to observe and interact with one another [67.4]. Moreover, people are highly attuned to human characteristics, such as the sound of human voices and the appearance of human faces and body motion [67.5–7]. Infants show preferences for these types of stimuli at a young age, and adults appear to use specialized mental resources when interpreting these stimuli. By mimicking human characteristics, humanoid robots can engage these same preferences and mental resources.

Humanity's interest in itself has been reflected in media as diverse as cave paintings, sculpture, mechanical toys, photographs, and computer animation. Artists have consistently attempted to portray people with the latest tools at their disposal. Robotics serves as a powerful new medium that enables the creation of artifacts that operate within the real world and exhibit both human form and behavior [67.8].

Popular works of fiction have frequently included influential portrayals of humanoid robots and human-made humanoid creatures. For example, *Karel Čapek's* science fiction play *Rossum's Universal*

Robots (R.U.R.) from 1920 centers around the story of artificial people created in a factory [67.9]. Many other works have included explicit representations of humanoid robots, such as the robot Maria in *Fritz Lang's* 1927 film *Metropolis* [67.10], and the thoughtful portrayal of humanoid robotics by *Isaac Asimov* in works such as *The Caves of Steel* from 1954 [67.11]. The long history of humanoid robots in science fiction has influenced generations of researchers, as well as the general public, and serves as further evidence that people are drawn to the idea of humanoid robots.

67.1.3 Understanding Intelligence

Many researchers in the humanoid robotics community see humanoid robots as a tool with which to better understand humans [67.3, 12]. Humanoid robots offer an avenue to test understanding through construction (*synthesis*), and thereby complement the *analysis* provided by researchers in disciplines such as cognitive science.

Researchers have sought to better imitate human intelligence using humanoid robotics [67.13]. Developmental psychologists, linguists, and others have found strong links between the human body and human cognition [67.14]. By being embodied in a manner similar to humans, and situated within human environments, humanoid robots may be able to exploit similar mechanisms for artificial intelligence (AI). Researchers are also attempting to find methods that will enable robots to develop autonomously in a manner akin to human infants [67.15]. Some of these researchers use humanoid robots that can physically explore the world in a manner similar to humans [67.16].

67.1.4 Human Environments

People inhabit environments that accommodate human form and human behavior [67.17, 18]. Many important everyday objects fit in a person's hand and are light enough to be transported conveniently by a person. Human tools match human dexterity. Doors tend to be a convenient size for people to walk through. Tables and desks are at a height that is well matched to the human body and senses. Humanoid robots can potentially take advantage of these same accommodations, thereby simplifying tasks and avoiding the need to alter the environment for the robot [67.19]. For example, humanoid robots and people could potentially collaborate with one another in the same space using the same tools [67.20]. Humanoid robots can also interface with machinery that does not include drive-by-wire controls, as shown by the teleoperated robot in the cockpit of a backhoe in Fig. 67.1 [67.21].

Robots with legs and human-like behavior could potentially traverse the same environments that humans traverse, such as rugged outdoor environments and the industrial plant shown in Fig. 67.2, which has stairs and handrails designed for human use [67.22]. In addition to mobility advantages, legs have the potential to help in other ways. For example, legs could enable a humanoid robot to change its posture in order to lean into something, pull with the weight of its body, or crawl under an obstacle [67.23, 24].

The Fukushima Daiichi nuclear disaster, which occurred in March 2011 in Japan, is a compelling example scenario for robots. The disaster resulted in human environments that were unsafe for humans. Robots capable of performing diverse tasks in these environ-

ments via remote control would have been valuable. Future humanoid robots may be able to access similar environments using narrow passageways, ladders, and other environmental features designed for people (Fig. 67.3). Likewise, they may be able to remotely perform tasks involving control panels, valves, and tools designed for people. This type of scenario

Fig. 67.1 The humanoid robot HRP-1S (HRP: humanoid robot project) driving a backhoe (courtesy Kawasaki Heavy Industries, Tokyu Construction and National Institute of Advanced Industrial Science and Technology (Japan) (AIST)). The robot can be teleoperated by a human operator to control the backhoe remotely. The same robot could potentially interface with many different unmodified machines

Fig. 67.2 HRP-1 operating in a mockup of an industrial plant (courtesy Mitsubishi Heavy Industries)

Fig. 67.3 An image of supposed disaster-response scenario DARPA Robotics Challenge

Fig. 67.4 The humanoid robot HRP-2 dancing with a human (after [67.25]). The human is a master of a traditional Japanese dance whose dancing was recorded by a motion-capture system, and transformed for use by the robot

Fig. 67.5 Actroid (courtesy Kokoro), an android designed for entertainment, telepresence, and media roles

Fig. 67.6 Atlas robot provided as a platform for the DARPA Robotics Challenge (courtesy Boston Dynamics)

has inspired the DARPA (Defense Advanced Research Projects Agency) Robotics Challenge in which robots will compete by performing related tasks. Notably, DARPA plans for some teams to compete using Atlas humanoid robots from Boston Dynamics Fig. 67.6.

67.1.5 Human Interaction

People are accustomed to working with other people. Many types of communication rely on human form and behavior. Some types of natural gestures and expression involve subtle movements in the hands and face (Chap. 72). People can interpret eye gaze and facial expressions without training. Humanoid robots can potentially simplify and enhance human–robot interaction by taking advantage of the communication channels that already exist between people.

Similarly, people already have the ability to perform many desirable tasks. This task knowledge may be more readily transferred to humanoid robots than to a robot

Fig. 67.7 Petman is a humanoid robot that Boston Dynamics developed to test chemical protection clothing for the US military (after [67.26])

with a drastically different body. This is especially true of cultural actions centered around the human form (Fig. 67.4).

67.1.6 Entertainment, Culture, and Surrogates

Humanoid robots are inherently appropriate for some applications. For example, robots that resemble humans could play roles in entertainment, such as theater, theme parks, and companionship for adults (Fig. 67.5). Realism in form and function could make humanoid robots preferable to wax figures and animatronics.

A humanoid robot could serve as an avatar for telepresence, model clothing, test ergonomics, or serve other surrogate roles that fundamentally depend on the robot's similarity to a human. For example, Boston Dynamics developed the humanoid robot Petman to test clothing that is intended to protect military personnel from chemical agents (Fig. 67.7). Robotic prostheses and cosmeses also have a close relationship to humanoid robotics, since they seek to directly replace parts of the human body in function and form (Chap. 64).

67.2 History

There is a long history of mechanical systems with human form that perform human-like movements. For example, Al-Jazari designed a humanoid automaton in the 13th century [67.27], Leonardo da Vinci designed a humanoid automaton in the late 15th century [67.28], and in Japan there is a tradition of creating mechanical dolls called *Karakuri ningyo* that dates back to at least the 18th century [67.29]. In the 20th century, animatronics became an attraction

at theme parks. For example, in 1967 Disneyland opened its *Pirate's of the Caribbean* ride [67.30], which featured animatronic pirates that play back human-like movements synchronized with audio. Although programmable, these humanoid animatronic systems moved in a fixed open-loop fashion without sensing their environments.

In the second half of the 20th century, advances in digital computing enabled researchers to incorporate

Fig. 67.8 (a) WABOT-1 (1973) and (b) WABOT-2 (1984; courtesy Humanoid Robotics Institute, Waseda University)

significant computation into their robots for sensing, intelligence, control, and actuation. Many roboticists developed isolated systems for sensing, locomotion, and manipulation that were inspired by human capabilities. However, the first humanoid robot to integrate all of these functions and capture widespread attention was Waseda robot (WABOT-1), developed by Ichiro Kato et al. at Waseda University in Japan in 1973 (Fig. 67.8).

The WABOT robots integrated functions that have been under constant elaboration since: visual object recognition, speech generation, speech recognition, bi-manual object manipulation, and bipedal walking. For instance, WABOT-2's ability to play a piano, publicized at the Tsukuba Science Expo in 1985, stimulated significant public interest.

In 1986, Honda began a confidential project to create a humanoid biped. Honda grew interested in humanoids, perhaps seeing in them devices of complexity comparable to cars with the potential to become high-volume consumer products one day. In 1996, Honda unveiled the Honda Humanoid P2, the result of this confidential project. P2 was the first full-scale humanoid capable of stable bipedal walking with onboard power and processing. Successive designs reduced its weight and improved its performance (Fig. 67.9). Compared to humanoids built by academic laboratories and small manufacturers, the Honda humanoids were a leap forward in sturdiness, using specially cast lightweight high-rigidity mechanical links, and harmonic drives with high torque capacity.

In parallel with these developments, the decade-long *Cog project* began in 1993 at the MIT Artificial Intelligence laboratory in the USA with the intention of

Fig. 67.9 (a) Honda P2 (180 cm tall, 210 kg), (b) P3 (160 cm, 130 kg), and (c) advanced step in innovative mobility (glossnoidx-ASIMO advanced step in innovative mobility) (120 cm, 43 kg) (after [67.31]; courtesy Honda)

Fig. 67.10 The humanoid robot Cog used neural oscillators in conjunction with compliant torque-controlled arms to perform a variety of everyday tasks with human tools, such as crank turning, hammering, sawing, and playing a snare drum (after [67.32]; courtesy Sam Ogden)

creating a humanoid robot that would, *learn to think by building on its bodily experiences to accomplish progressively more abstract tasks* [67.13]. This project gave rise to an upper-body humanoid robot whose design was heavily inspired by the biological and cognitive sciences (Fig. 67.10). Since the inception of the Cog project, researchers across the world have initiated many humanoid robotics projects and formed communities devoted to developmental robotics, autonomous mental development (AMD [67.33]), and epigenetic robotics [67.34].

As of the early 21st century, a large number of companies and academic researchers have become involved with humanoid robots and created new humanoid robots with distinctive characteristics.

67.3 What to Immitate?

Humanoid robots come in a variety of shapes and sizes that immitate different aspects of human form and behavior (Fig. 67.11). As discussed, the motivations that have driven the development of humanoid robots vary widely. These diverse motivations have led to a variety of humanoid robots that selectively emphasize some human characteristics, while deviating from others.

67.3.1 Body Parts

One of the most noticeable axes of variation in humanoid robots is the presence or absence of body parts. Some humanoid robots have focused solely on the head and face, others have a head with two arms mounted to a stationary torso, or a torso with wheels (for example, Fig. 67.12). Some humanoid robots even combine a highly-articulate face with arms, legs, and a torso.

67.3.2 Mechanics

Humanoid robots immitate various mechanical aspects of the human body, such as its kinematics, dynamics, geometry, material properties, and actuation. As such, humanoid robotics is closely related to the field of human biomechanics.

Humanoid robots often consist of rigid links with kinematics that approximate the kinematics of the human musculoskeletal system. Even a rigid-link model of human kinematics can have a very high number of degrees of freedom (DOF). A humanoid robot typically immitates degrees of freedom that are pertinent to its intended use. For example, humanoid robots rarely attempt to immitate the human shoulder's ability to translate or the flexibility of the human spine [67.35, 36]

Fig. 67.11 Kismet is an example of a humanoid head for social interaction

The human hand serves to further illustrate these issues. Modern humanoid robots frequently have two arms, each with seven degrees of freedom, but their hands vary considerably (Chap. 19). The human hand is highly complex with over 20 DOFs (i.e., approximately four DOFs per finger and a five-DOF thumb) in a very compact space with a compliant exterior, dense tactile sensing, and low distal mass. Researchers have approximated the human hand with varying levels of accuracy, including the anatomically correct testbed (ACT) hand, the 20-DOF Shadow Hand, the 12-DOF DLR-Hand-II (DLR: Deutsches Zentrum für Luft- und Raumfahrt), the 11-DOF Robonaut hand, and the 2-DOF Cog hand [67.37–41]. The ACT hand represents the high-fidelity end of the spectrum, since it approximates the bone structure, inertial properties, kinematics, and actuation of the human hand.

Actuation is another property of humanoid robots that varies considerably. Human actuation consists of a complex, highly-redundant system of variable-stiffness muscles. In contrast, many humanoid robots use a stiff, position-controlled actuator at each joint. There are early exceptions, such as the use of series elastic actuators in Cog's arms [67.32, 42], and various forms of compliant actuation have now become common in the arms of humanoid robots.

67.3.3 Sensors

Humanoid robots have made use of a variety of sensors including cameras, three-dimensional (3-D) cameras, laser rangefinders, microphone arrays, lavalier microphones, and pressure sensors. Some researchers choose to immitate human sensing by selecting sensors with

Fig. 67.12 The NASA (National Aeronautics and Space Administration) Robonaut consists of an upper body placed on a wheeled mobile base

clear human analogs and mounting these sensors on the humanoid robot in a manner that mimics the placement of human sensory organs. As discussed in Sect. 67.6, this is perhaps most evident in the use of cameras. Two to four cameras have often been mounted within the heads of humanoid robots with configurations similar to human eyes.

The justifications for this bias towards human-like sensing include the impact of sensing on natural human–robot interaction, the proven ability of the human senses to support human behavior, and aesthetics. For example, with respect to human–robot interaction, nonexperts can sometimes interpret the functioning and implications of a human-like sensor, such as a camera, more easily. Similarly, if a robot senses infrared or ultraviolet radiation, the robot can see a different world than the human. With respect to behavior, placement of sensors on the head of the robot allows the robot to sense the world from a vantage point that is similar to that of a human, which can be valu-

able for finding objects that are sitting on a desk or table.

Prominent humanoid robots have added additional sensors without human analogs. For example, Kismet used a camera mounted in its forehead to augment the two cameras in its servoed eyes, which simplified common tasks such as tracking faces. Similarly, versions of [ASIMO](#) have used a camera mounted on its lower torso that looks down at the floor in order to simplify obstacle detection and navigation during locomotion.

67.3.4 Other Characteristics

Other common forms of variation include the size of the robot, the extent to which the robot attempts to appear like a human, and the activities the robot performs. The remainder of this chapter provides examples from three active areas of humanoid robotics research: locomotion, whole-body activities, and morphological communication.

67.4 Locomotion

Bipedal walking is a key research topic in humanoid robotics (see also Chap. 48, *Legged Robots*, for a review of this topic in the context of locomotion in general). Legged locomotion is a challenging area of robotics research, and bipedal humanoid locomotion is especially challenging. Some small humanoid robots are able to achieve statically stable gaits by having large feet and a low center of mass, but large humanoids with a human-like weight distribution and body dimensions typically need to balance dynamically when walking bipedally.

67.4.1 Bipedal Locomotion

Currently the dominant methods for bipedal legged locomotion with humanoids make use of the zero-moment point ([ZMP](#)) criterion to ensure that the robot does not fall over [67.43]. As discussed in detail in Chap. 48, control of the robot's body such that the [ZMP](#) sits within the support polygon of the robot's foot ensures that the foot remains planted on the ground, assuming that friction is high enough to avoid slipping. The [ZMP](#) can be used to plan walking patterns that make the robot dynamically stable while walking. Conventionally, biped locomotion had been offline generated by solving an ordinally differential equation with respect to the motion of the [COG](#) (center of gravity) given a desired trajectory of the [ZMP](#).

Recently, several extensions have been done for the [ZMP](#) based biped gait generation as shown in the following:

Realtime Walking Pattern Generation

By solving the ordinally differential equation in realtime, biped gait is generated in realtime [67.44, 45]. Since the realtime walking pattern generator enables us to change the landing positions of foot in realtime, it is used in various situations; in [67.46], the landing position of the foot changes in accordance with the hand reaction force as will be described more concretely in the subsection of *manipulation*. As shown in Fig. 67.13 [67.47], the walking pattern is generated in realtime in accordance with the amount of external disturbance applied to the robot. In this case, after the torso of a robot is pushed by a human, biped gait for a few steps is generated in realtime to recover the balance. In [67.48], the humanoid robot [ASIMO](#) walks in the environment with moving obstacles. By using the estimation of the object motion, the walking pattern of the robot is generated in realtime. Fig. 67.14 [67.49] shows the biped locomotion on uneven terrain. In this experiment, the shape of the environment is measured by a laser range sensor. According to the shape information of the environment, the landing position on uneven terrain is calculated in realtime.

Fig. 67.13 Experiment of push recovery

Running
By additionally considering the flight phase to the ZMP based walking pattern generator, running motion of biped robot is generate [67.50–52]. Fig. 67.15 [67.52] shows an example of running motion by a biped humanoid robot. Running motion

Fig. 67.14 Experiment on biped gait on uneven terrain

of a human-sized humanoid robot with 7 km/h is realized.

Extension of ZMP Based Method
Although the ZMP is a two dimensional information defined for the interaction between a robot and the ground surface, a robot applies 6 dimensional force/moment onto the ground. Hence, just by regulating the position of the ZMP, it is impossible to control all dimension of the interaction force/moment. More concretely speaking, the robot may slip on the ground surface or may loose contact with the ground. Research on biped locomotion considering full 6 dimensional force/moment has been don [67.53, 54].

Human-Like Walking Motion
The biped locomotion generated just by using the ZMP may not be a human-like one. Challenge has been done to generate a human-like biped gait of a humanoid robo [67.55]. Fig. 67.16 [67.55] showws a biped locomotion where single toe support, knee stretching and human like swing leg trajectory are applied. It is compared with the human walking motion where the model belongs to *Walking Studio Rei*.

Force/Moment Controller
Bipedal walking needs to be robust to unexpected disturbances encountered during the execution of planned

Fig. 67.15 Example of running motion

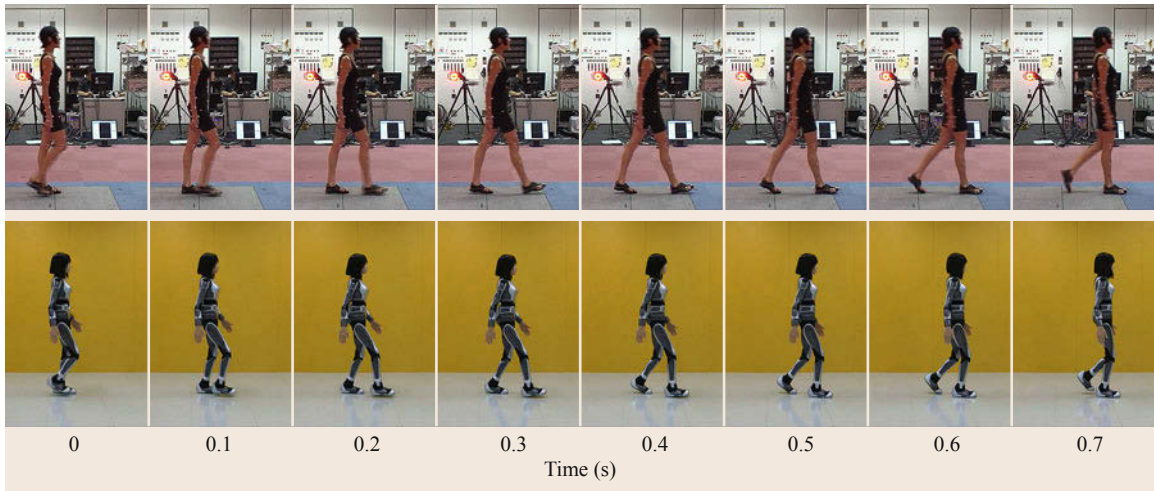

Fig. 67.16 Human like walking motion compared with human motion

walking patterns. In these situations, walking can sometimes be stabilized with feedback control and appropriate sensin [67.56]. Many humanoid robots, such as Honda's [ASIMO](#), make use of accelerometers, gyroscopes, and six-axis force/torque sensors to provide feedback to the robot during locomotion.

Force/torque sensors have long been applied to manipulators for the implementation of force control, but force/torque sensors with sufficient robustness to handle foot impact for a full-size humanoid robot are relatively new. When the foot of the robot touches down, the foot receives an impact which can disturb its walking. This impact can be rather large, especially when the robot is walking quickly. Some feet now incorporate a spring and damper mechanism as shown in [Fig. 67.17](#) in order to mitigate these problems.

Passive-Gait-Based Approach

Alternative to the [ZMP](#)-based approach, researchers have begun to use the principles of bipedal passive-dynamic walkers to develop powered bipedal walkers

Fig. 67.17 Example of a humanoid foot structure for legged locomotion that uses compliance and force/torque sensing

that walk with high efficiency in a human-like way by exploiting natural dynamics ([Fig. 67.18](#) [67.57]).

67.4.2 Other Various Locomotion Styles

Most humanoid robots have two legs and two arms. Here, in addition to the legs, the arms can be used to

Fig. 67.18 These robots from Delft, MIT and Cornell (left to right) are designed to exploit their natural dynamics when walking (after [67.57]; courtesy Steven H. Collins)

enhance the mobility of a humanoid robot. For example, when a robot walks while grasping a handrail, the contact could potentially increase the stability of the robot. Attempt [67.58] have been done to generate the motion of a humanoid robot by using the arms in addition to the legs to enhance its mobility of it. As shown in Fig. 67.19 [67.58], a humanoid robot walking on uneven terrain sometimes uses to increase the robot's stability.

A human-scale robot should expect to fall from time to time in realistic conditions. A humanoid robot may fall down due to a large disturbance even if the motion is planned carefully and a sophisticated feedback controller is applied to the robot. In this event, the robot could be damaged significantly during a fall, and could

also damage the environment or injure people who are nearby. An important area of research is how to control the robot's fall in order to gracefully recover or minimize damage. The Sony **QRIO** (Quest for cuRIOsity) can control its falling motions in order to reduce the impact of touch down [67.50], although it is of a relatively small size (which simplifies the problem). *Fujiwara* et al. developed a falling motion controller for a human-size humanoid robot that is falling backwards [67.59]. Figure 67.20 shows an example of a controlled falling motion. The general problem is still very much an active area of research. Similarly, there is also the issue of getting back up again [67.60] (Fig. 67.21).

67.4.3 Localization and Navigation Among Obstacles

In order for a humanoid robot to walk in unmodeled environments, localization and obstacle detection are essential. Wheeled robots encounter similar issues while navigating, but full bipedal humanoids have more-specialized requirements. For example, bipedal humanoids have the ability to control contact with the world through their highly articulate legs.

Artificial landmarks can simplify localization. As shown in Fig. 67.22, Honda's **ASIMO** uses a camera mounted on its lower torso that looks down at the floor to find artificial markers for position correction [67.61]. Accurate positioning is important for long-distance navigation and stair climbing, since slippage usually occurs while walking and accumulated positional and directional errors can lead to severe failures.

Obstacle avoidance is also an important function for locomotion. Disparity images generated by stereo vi-

Fig. 67.19 Humanoid robot walking on uneven terrain by utilizing hand contact

Fig. 67.20 Example of controlled falling-down motion

Fig. 67.21 The humanoid robot **HRP-2P** getting up from a lying-down position ►

sion have been utilized for this purpose. For example, the plane segment finder [67.62] developed by *Okada et al.* helps detect traversable areas. Figure 67.23 shows the result of detecting clear areas of the floor plane appropriate for gait generation.

Humanoids require a great deal of computation due to the need for sophisticated sensing and control. Customized computational hardware may help mitigate this problem. For example, Sony's humanoid robot **QRIO** is equipped with a field-programmable gate array (**FPGA**) to generate disparity maps in real time from the stereo cameras. This real-time vision system has been used to detect floor areas, stair steps, and obstacles for navigation [67.63, 64].

67.4.4 Generating Motions when in Contact with an Object

Many approaches to whole-body motion generation assume that the robot is only in contact with the ground. When a humanoid robot's hands make contact with the environment, it can no longer maintain balance using the conventional **ZMP** property defined by the center of pressure of the supporting feet [67.65]. This leads to significant challenges for whole-body activities, especially since the properties of the environment with which the robot is making contact may not be known in advance.

Harada et al. have introduced generalized **ZMP** (**GZMP**) as a method of handling some of these issues, such as the hand reaction forces generated from contact with the environment [67.66]. Researchers have developed methods that directly make use of the six-dimensional force/torque acting on the robot at the hands, which can be sensed with conventional force/torque sensors placed at the wrists [67.67]. Researchers have also developed specialized methods for generating stable robot motion while an object is being manipulated [67.46, 65, 68–70].

Fig. 67.22 **ASIMO** and artificial landmarks on the floor

Fig. 67.23 Plane segment finder for detecting traversable floor area

Fig. 67.24 (a–h) Lifting an object while moving the waist to compensate for the load (after [67.71])

Carrying an Object

In a manner analogous to the previously described methods, coarse motions that do not consider the hand reaction forces can be modified [67.65, 68, 71, 72]. Figure 67.24 shows an experimental result of carrying an object that weighs 8 kg [67.71]. Based on measurements of the hand reaction force, the position of the waist is modified to compensate for the load and maintain stability.

Pushing an Object

As another example of using force sensing to adapt behavior, consider the problem of pushing a large object placed on the floor. For such a task, if the gait

Fig. 67.25 (a–h) Example of pushing manipulation and cooperation (after [67.46])

pattern is determined before the robot actually moves, the robot may not stay balanced if the weight of the object or the friction coefficient between the object and the floor is different from the predicted values. To address this problem, the gait pattern can be adaptively changed depending on the output of a force sensor at the end of the arms in order to handle changes in the object's weight and the friction coefficient [67.46].

Figure 67.25 shows an experimental result for this approach [67.46]. In the experiment, the table weighs about 10 kg. Even though the motion of the table is disturbed externally during the experiment, the robot stays balanced by adaptively changing its gait pattern based on the measured forces.

67.5 Whole-Body Activities

The two previous sections have focused on humanoid locomotion and manipulation separately. This section outlines whole-body motions that require coordinated control of arms and legs to perform various tasks, such as carrying a bulky objects, climbing a ladder, or going through narrow spaces with contact supports on the environment. Humanoid motion is characterized by their redundancy and underactuation (Chaps. 10 and 17). Unlike fixed industrial robots, it has a floating base (usually it is set at the pelvis) that can only be controlled through the leg locomotion or multiple contact motion involving arms and legs. It is therefore essential how to define the desired task and to generate the motion that achieves it. Since humanoids have a redundant structure, a general approach is first to generate coarse motion, and then to transform it into a whole-body coordinated joint trajectory that is executed by a controller maintaining the stability through sensor feedback, as illustrated in Fig. 67.26. The first half of this section addresses the first two components of this general approach.

The latter half of this section deals with issues related to various complex whole-body motion that the basic conversion methods addressed in Sect. 67.5.2 could not always resolve. Resolution of various concurrent tasks, including those expressed as inequality and dynamic constraints is presented in Sect. 67.5.3. This framework can be applied to a reaching task while keeping the visibility of the object, as well as footstep planning. Finally, motion generation including multiple contacts is introduced as an advanced topic in Sect. 67.5.4. A wide variety of its application is expected to extend the activity fields of humanoids in cluttered environments where the humanoid should maintain its balance by supporting its body on non-coplanar contact points.

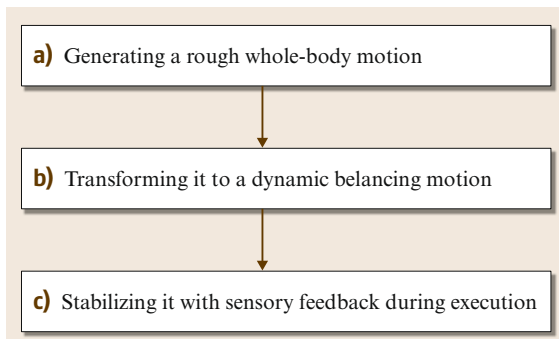

Fig. 67.26 Overview of motion-generation stages for a balancing robot

67.5.1 Coarse Whole-Body Motion

There are several ways to generate coarse humanoid motion:

1. Using motion capture system
2. Using graphical user interface (GUI)
3. Using automated motion planning
4. Using abstract task specification.

Using Motion Capture System

As humanoid robot has a human-like structure, a natural and common way of motion generation is using measured human motion. Motion retargeting from recorded human motion to digital characters is a well-studied area in computer animation. Typically a human subject performs actions while wearing easily detected markers on his or her body. The motion of these markers is recorded by cameras placed in the room, and software then infers the 3-D positions of these markers over time. A number of studies have been reported to convert the capture motions to humanoid whole-body motions through learning [67.73] and optimization [67.74, 75]. Figure 67.27 shows an example: the captured motions of a woman performing a Japanese traditional dance [67.76] that the performance in Fig. 67.4 is based on. Kinematic similarity allows using the captured motion as a reference for a humanoid's whole-body motion, by computing the corresponding joint angles from forming virtual links with several markers. However, due to dynamic differences, such as mass distributions and torque generation, captured motions are generally not stable nor feasible when applied to a humanoid. It is therefore necessary to adapt them to humanoid body as explained in Sect. 67.5.2.

Using GUI

Tools such as those used in character animation for computer graphics can also be used to design movements for humanoid robots. If the designer were forced to control each of the many degrees of freedom independently or to takes care of the balance, the process would be tedious and inefficient. One solution that enables non robotics expert to design robot motion is key-pose based approach on GUI, which allows the designer to define the *key-poses* of the desired motion with the help of inverse kinematics of the end effectors. The interface take care of the interpolation and dynamic balance compensation so that the input motion is feasible for the humanoid as explained later in Sect. 67.5.2. Figure 67.28 illustrates the overview of a GUI interface developed as *Choreonoid* for this purpose [67.77, 78].

Fig. 67.27 A sequence of captured motion of dancing (after [67.76])

Using Automated Motion Planning
The previous two methods are based on mainly joint angles from a motion capture system or a GUI. If the purpose of the robot motion is going from one configuration to another without collisions and how the humanoid moves does not really matter, automated motion planning can provide efficient solutions (Chaps. 36 and 47).

Fast path-planning techniques such as rapidly-exploring random trees (RRT) can compute basic collision-free postures with static balance [67.79, 80] or walking paths [67.81] automatically with a simplified model. Figure 67.29 illustrates a humanoid carrying an object whose lower body is modeled by a bounding box. Given geometric models of the humanoid and the environment, initial and goal configurations, the planning system automatically searches for a path free of collisions at both upper and lower bodies. This coarse path can be converted into dynamically stable whole-body motion a walking pattern generator including upper-body motion compensation as described in Sect. 67.5.2. For further reading on humanoid motion planning, the

readers are referred to a book dedicated to this subject [67.82].

Using Abstract Task Specifications
Tasks for a humanoid to execute are not always specified in the joint space, but often in the workspace. For instance, if the humanoid wants to grasp an object on the table or floor, this task is expressed as the hand position and orientation in Cartesian space [67.83–87]. Another example is teleoperation: it is easier for the operator to guide an operational point, such as the end-effector or the head of the humanoid, rather than to give a whole-body joint configuration [67.88]. These tasks are represented in an abstract way by a smaller number of DOF than the redundant structure of humanoid. Figure 67.30 shows a motion of bimanual manipulation based on abstract representation of motion as a sequence of attractor points acting in the task space [67.89].

On the other hand, other constraints such as balancing or joint limits should also be taken into account to generate a whole-body motion to achieve the task.

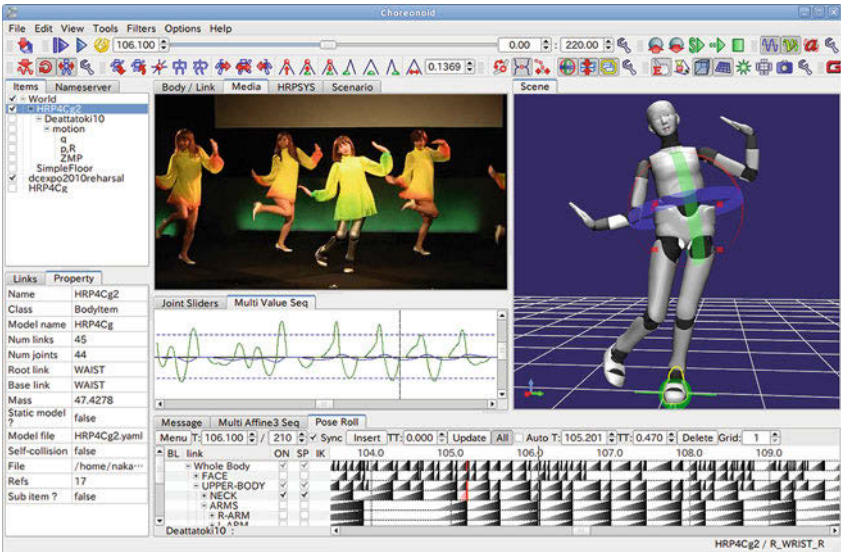

Fig. 67.28 A motion choreography tool working within the Choreonoid framework. In this tool, whole body motions of biped humanoid robots can be created with key-frame editing similar to computer graphics (CG) character animations (after [67.78])

Fig. 67.29 Humanoid modeled by rectangle box with a bar. In the first stage the geometric and kinematic path planner generates collision-free path for the 9-DOF system including robot waist on the plane (3-DOF) and object (6-DOF)

A mechanism is therefore necessary that derives a humanoid positioning as well as a whole-body target posture from the abstract goal specification. Whereas the previously introduced GUI including automatic balancing is useful for cases with large free space, cluttered environments require integration of search techniques to compute a valid whole-body posture from the task [67.90,91]. Motion generation for multiple tasks and constraints is later discussed in Sect. 67.5.3.

67.5.2 Generating Dynamically Stable Motions

The methods presented in Sect. 67.5.1 can be useful when generating coarse motions for a humanoid robot, such as dance performance, manipulating or walking. However, for some of these methods the motions generated will not take into account the dynamic stability of the robot, and may result in the robot falling over. This subsection presents some approaches for con-

verting coarse motions to dynamically-stable motions, dynamic balancing algorithms and task-balance functional decomposition. In the former approach, all the joints including upper body are involved for whole-body balancing based on the reference motion, like kicking motion that needs upper body motion compensation. The latter uses mainly lower body for balancing or walking while upper body takes care of the desired tasks such as manipulation.

Dynamic Balancing

A framework called autobalancer is one of the pioneering studies for the dynamic whole-body balancing for humanoids. It all joint angles at every sample in time by solving a quadratic programming (QP) optimization problem in order to convert a given motion to a balanced one [67.92]. This method can be effective for a motion in which static balancing is dominant, such as when the humanoid is standing. The autobalancer calculates a whole-body motion first by fixing the center of gravity (COG) on the vertical axis which passes through a point in the support polygon of the humanoid. Then it keeps inertia moments around the COG at acceptable values in order to satisfy the balancing conditions. This technique was combined with a fast sampling-based motion planner to derive a dynamically motion by exploring configurations with balance constraints [67.79].

Resolved momentum control (RMC) [67.93] is a framework for whole-body control based on the linear and angular momentum of the entire robot. The robot is regarded as a single rigid body whose linear and angular momentum is to be controlled. At each point in time, this framework uses least squares to find joint velocities that will achieve the desired linear and angular momentum of the robot. Elements of the momentum can also be left unspecified as free variables, which is often done in practice with elements of the angular momentum. In addition to elements of the momentum, resolved momentum control requires that desired velocities for the feet be specified. This method has been applied to teleoperation [67.88] or stable reaching or kicking motions [67.93]. Other methods like dynamics

Fig. 67.30 Bimanual manipulation by humanoid robot ASIMO based on a motion representation using attractor dynamics in task space (after [67.89])

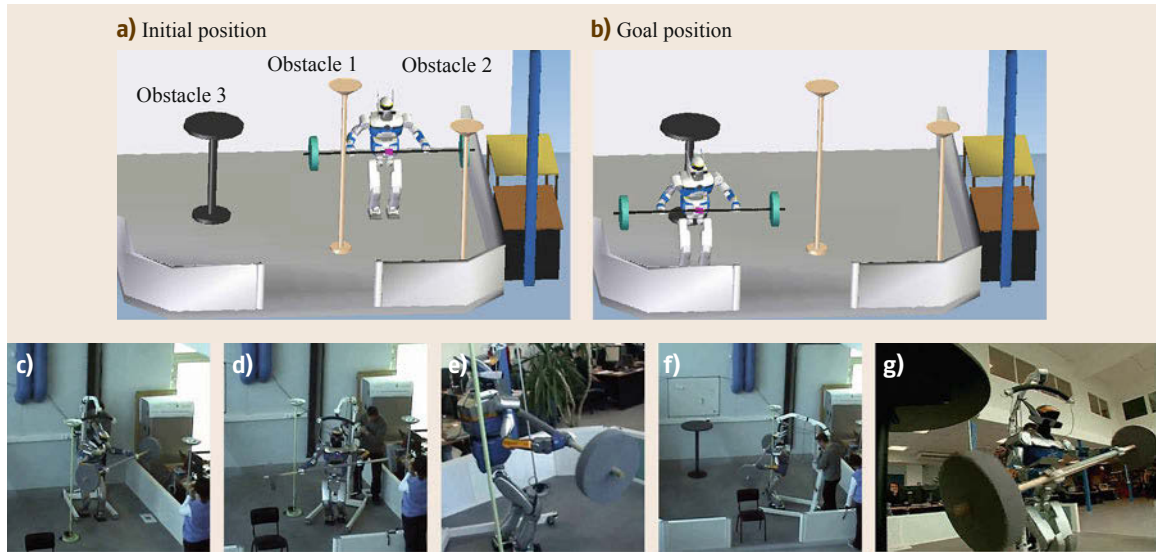

Fig. 67.31a–g A 3-D collision-free motion for bar-carrying task by humanoid robot HRP-2 from starting (a) an initial position to final configuration (goal position) (b) using whole-body motion (after [67.81]). The robot rotates the bar horizontally to make the bar go through a gap between poles whose distance is shorter than the of the bar (c–e). By making use of the concave part of the carried object (f) for 3-D collision avoidance, it arrives at the goal configuration with another avoidance motion (g) (VIDEO 594, VIDEO 598)

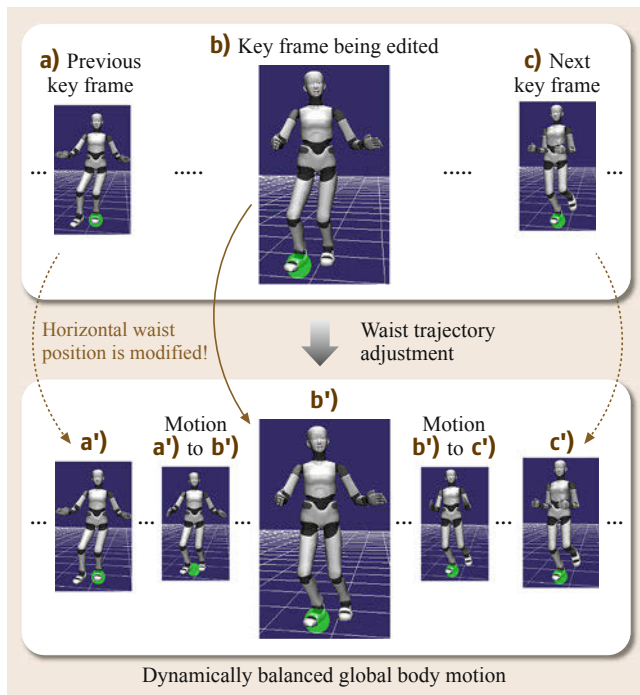

Fig. 67.32 Waist trajectory adjustment, which is automatically processed immediately after every time key poses are modified. As a result, horizontal waist positions of key poses are slightly modified and a dynamically balanced motion is obtained (after [67.77])

filter that makes reference motions dynamically feasible by a humanoid [67.94], upper-body motion compensation for Waseda bipedal humanoid (WABIAN) [67.95] have also been proposed as this type of approach.

Task-Balance Functional Decomposition

In this approach, dynamic stability is maintained during whole-body motion based on pattern generation or a balance compensation by the legs to maintain the ZMP inside the foot support area, while upper body is in charge of specified tasks such motions as manipulation or designed movement.

An iterative two-stage motion planning method has been proposed for a humanoid to perform manipulation and locomotion at the same time [67.81]. At the first stage, the motion planner generates the upper-body motion with a walking path of the bounding box of the lower body as in Fig. 67.29. The second stage overlays the desired upper-body motion on the dynamically stable walking motions generated by a dynamic walking pattern generator based on preview control of ZMP for a linear inverted pendulum model [67.96] (Chap. 48 and Sect. 67.4). This upper-body motion during walking induces errors in resulting ZMP from the reference, which may make the humanoid instable. By applying the preview control again to this ZMP error the necessary compensation motion can be computed as a horizontal offset on the waist position. If the resulting

whole-body motion is not collision-free, the planning process goes back to the first stage to reshape and this procedure is repeated until a valid motion is obtained. Figure 67.31, VIDEO 594 and VIDEO 598 show the resulting collision-free manipulation motion of a bar-shaped object in an environment populated with obstacles.

Lower-body motion compensation for dynamic balance is also used for GUI-based motion designing [67.77]. The GUI accepts a sequence of key-poses for the desired motion as the input and interpolates between them to compute the whole-body motion of the humanoid. Since the generated motion is not dynamically stable in general, both the key poses and the interpolated motion are adjusted to be dynamically balanced by applying the waist trajectory adjustment in such a way that the trajectory of the ZMP from body motion is always inside the foot support area. The adjustment only modifies the horizontal waist position of the key poses and the interpolated ones, for the adjusted motion to be as close as the original one (Fig. 67.32). The adjustment is automatically and immediately done every time a user has finished an edit operation so that the user can see the resulting motion.

67.5.3 Generating Whole-Body Motions with Various Tasks

The main purpose of the methods in previous section was to make the given coarse motion dynamically stable. One can think of a case the task is only given in an abstract manner, for instance reaching the end-effector in specified position and orientation in workspace, or aligning a camera axis in a direction. This section takes a step forward in order to generate automatically the motion to achieve the specified tasks by taking into account such constraints as balance, foot positions or joint limits at the same time. Generalized inverse kinematics technique with task priority and its extension is utilized as a key tool for local whole-body motion generation (Chap. 10).

The main particularities of humanoid robot from the viewpoint of inverse kinematics are the following: necessity of dynamic balancing, changing fixed root joint and floating base frame. Those issues should be dealt with appropriately depending on the task of the robot. Some extensions for more complex tasks including inequality constraints, footstep planning and dynamics are also mentioned at the last part of this section.

Dynamic Balancing and Walking

Some examples are shown the whole-body motion generation based on task priority generalized inverse kinematics. As shown in Chap. 10, this framework ac-

complishes first the task with the highest priority and then tries to achieve those with lower priority at the best in the null space of the higher-priority tasks.

Tasks are specified locally as a velocity in workspace, such as hand velocity to reach the target. The balance constraint can therefore be expressed as the velocity of the center of mass (COM). The ZMP-based pattern generator has the advantage that it outputs the velocity of the COM of dynamically stable walking motion from the reference ZMP trajectory, which can be easily integrated into this inverse kinematics framework by using COM Jacobian [67.97]. Figure 67.33 shows the whole-body reaching motion including a step to take a ball localized by a vision system [67.85]. The high priority is assigned to COM and foot motion to avoid falling in this example. As can be seen, the legs are used not only for stepping but also bending to reach a lower position in a manner coordinated with the upper body. The left arm moves backwards as the result of balancing task. Whole-body motions for manipulation of daily-life tools [67.84] or object pushing/lifting [67.98–100], and also for self-collision avoidance [67.101] have been implemented also based on a similar framework.

Another example is given in Fig. 67.34, VIDEO 595 and VIDEO 599 where the humanoid

Fig. 67.33 (a–f) A whole-body grasping motion generated through task-priority generalized inverse kinematics (after [67.85]). Upper and lower bodies coordinate to achieve the desired grasping task while making a step and maintaining the balance

Fig. 67.34a–f Experiments of whole-body *pivoting* manipulation. Starting from the initial position (a) with obstacle at right-hand side, the humanoid robot manipulates the object backwards away from the wall (b). After switching motion direction to forward (c), the robot continues to manipulate the object to the goal position by avoiding the obstacle (the hanger) (d–f) (👁 VIDEO 595, 👁 VIDEO 599)

Fig. 67.35 Footstep planning modeled as a whole-body inverse kinematic problem (after [67.102]) (👁 VIDEO 596, 👁 VIDEO 600)

execute *pivoting* manipulation to carry a bulky object without lifting [67.86]. In this case, a coarse path of the object towards its goal position is first planned to compute the trajectory of the hands that perform the manipulation. Then foot positions are determined along the object path, from which the COM trajectory is derived using the dynamic walking pattern generator. Those tasks are provided to the inverse kinematics to generate the coordinated arm and leg motion for this complex manipulation. In addition to the dynamic balance, the change of the root joint is also considered to compute the whole-body motion when the support leg changes during walking. The same framework has been applied to a motion for catching a moving object

during walking where the task of visual tracking by the end-effector is integrated with dynamic walking motion [67.103].

Floating base frame of a humanoid sometimes brings difficulties in determining the whole-body configuration from a specific abstract task specified in workspace. In the methods mentioned above, the goal configuration is derived as a result of repeated computation of local generalized inverse kinematics. However, there are often cases where goal whole-body configurations is first needed to be used popular motion planning techniques searching in configuration space such as sampling-based planning. Some methods that derive the goal configuration based on inverse kinematics can be useful for this purpose [67.90, 91, 104] or a precomputed reachability map that characterizes the capacity of reaching in discretized workspace around the robot [67.105, 106].

Extensions for Complex Tasks

The whole-body motion generation with tasks can be extended to cope with more complex tasks such as stepping and those expressed as inequality or dynamic constraints.

One extension particular to humanoid is incorporating stepping in the framework of whole-body generalized inverse kinematics. Kanoun et al. [67.102] introduced an augmented robot structure by introducing *virtual* planar links attached to a foot that represents footsteps as illustrated in Fig. 67.35, 👁 VIDEO 596 and 👁 VIDEO 600. This modeling makes it possible to solve the footstep planning as a problem of inverse kinematics, and also to determine the final whole-body configuration. After planning the footsteps, the dynamically stable whole-body motion including walking can be computed by using the method presented earlier.

Task-priority generalized inverse kinematics for redundant robots in Sect. 10.3 usually models tasks as equalities so that the operational points can achieve the desired velocity. However, tasks are sometimes given as inequalities: keeping the hand out of some area to avoid collisions or robot view obstruction, respecting joint limits, or maintaining the COM inside the foot support area. Inequality tasks have usually been transformed into more restrictive equality constraints through potential fields. A method for extending the task-priority inverse kinematics for those inequality tasks is proposed to remove this limitation based on a sequence of QP optimization [67.87]. This method searches for the optimal sets for the sequence of QPs by minimizing the error to the desired equality tasks in such a way that inequality ones can also be satisfied at a desired priority. This method allows the humanoid to perform such

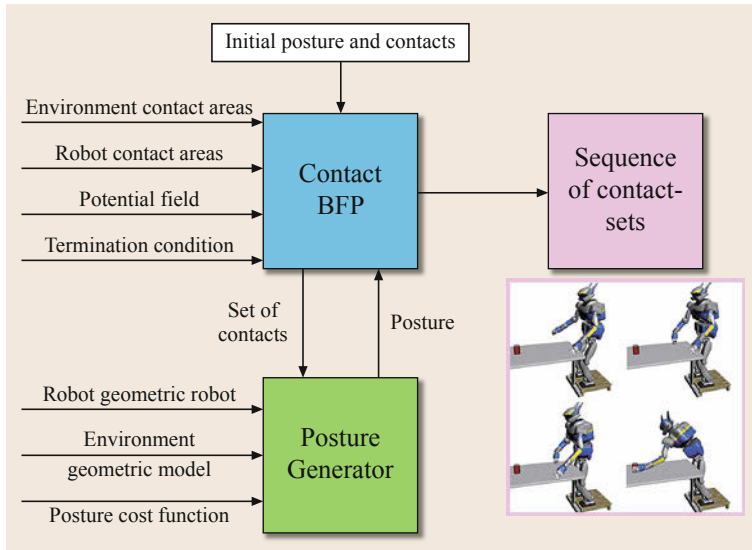

Fig. 67.36 Framework of contact motion planner composed of contact best-first-planner (BFP) and posture generator (after [67.107])

Fig. 67.37 A sequence of planned whole-body motion including multiple contacts on a irregular terrain (after [67.108])

a task of reaching its arm towards an object on the floor without obstructing its view.

This approach based on cascaded QP can be generalized to generate whole-body motions including dynamic equality and inequality tasks [67.109]. In addition to inverse kinematics considered so far, inverse dynamics is also integrated to the task-priority whole-body motion generation framework. By using this method, the dynamic balance can be addressed directly without converting the dynamic ZMP constraint into COM velocity via a pattern generator. This approach assumes a torque-controlled humanoid as opposed to position controlled ones that are often the case for platform currently used. However, dynamic whole-body motion generation with various tasks is being actively studied owing to not only recent progress of robot hardware [67.110] but also increasing interests on more complex tasks including multiple contacts presented in the next section.

67.5.4 Generating Motions Including Multiple Contacts

The whole-body motions presented so far basically supposes only the contacts between the humanoid's feet and the floor. Looking at our daily life however, contacts other than with feet occurs often, for example pass

through narrow spaces or to support the body when reaching a distant place on the desk. Since a humanoid is high affinity to environments designed for humans, its application fields could be expanded by exploiting the contacts as much as possible rather than by avoiding them as is often the case in motion planning. This section addresses planning and control of whole-body motions with multiple contacts that have been intensively studied in recent years. The role of planner is to derive a global sequence of configuration with multiple contacts to reach the goal, whereas the controller generates dynamically stable motions to transit from one contact state to another.

Motion Planning for Multiple Contacts

Multicontact nongaited have been proposed that are applicable to legged robots including humanoids [67.107, 108, 112]. By defining a stance as a finite set of contacts between the robot and the environment, the planner generates a sequence of stances that can reach the goal. During the planning, possible transitions from a stance are explored by sampling another stance with a feasible and stable robot configuration, as shown in Fig. 67.36 [67.107]. Figure 67.37 shows a resultant locomotion planned using this planning method [67.108]. A more generalized framework is proposed to deal with multirobot and multiobject systems [67.113]. This

Fig. 67.38 Dynamic multicontact motion generated through global trajectory optimization (after [67.111], VIDEO 597)

generalization allows for a common description and treatment of locomotion and manipulation problems, either for a single robot or for multiple collaborating robots.

The output of the planner is a sequence of statically stable contact stances that can be executed through quasi-static motions. In order to generate fast but dynamically stable motions, a global optimization approach has been proposed [67.111]. This method parameterizes joint trajectory by B-Spline function to convert the infinite trajectory problem to semi-infinite one so that optimization technique can be applied. The whole-body motion is generated through nonlinear optimization to minimize square torque and execution time, by taking into account such constraints as joint torque limits and dynamic multiple contact stability. As a result, the generated motion is much faster than quasi-static ones. An example of resultant motion is shown in Fig. 67.38 and VIDEO 597. Trajectory optimization approach can also be applied for lifting of a very heavy object by generating a weight-lifting motion by always respecting physical constraints [67.114].

Even though the feasibility of multicontact motions like in Fig. 67.38 have been validated with experiments, the optimization process is time-consuming and cannot cope with errors or disturbances during execution. It is therefore necessary to build a controller that ensures execution of multicontact whole-body motions.

Stability Measure for Motion with Multiple Contacts

Before discussing controller, it is worth mentioning first dynamic stability measure for non coplanar contacts and its usage. Although the ZMP is well-known dynamic stability criteria, it can only be applied to contacts on a flat plane. Stability margin for mobile robots [67.118] is only applicable for static gait for legged robots. A generalized version of ZMP (GZMP)

Fig. 67.39 Walking on a rough terrain using a support of arm on a handrail (after [67.115])

has therefore been proposed [67.119] by extending the ZMP by considering interaction forces other than floor-foot contacts. The stable region for multiple contacts can be obtained by considering the infinitesimal displacement and the moment about the edges of the convex hull of the supporting points. Hirukawa et al. proposed another criterion called contact wrench sum (CWS), which is the sum of the gravity and the inertia wrench applied to the COG of the robot. The humanoid is stable if it is inside the polyhedral convex cone of the contact wrench between the feet of a robot and its environment [67.115, 120]. Based on this criterion, walking

Fig. 67.40 Real-time simulation of a multicontact behavior with user-enabled interactive control of the robot's right hand. A virtual linkage model is overlaid capturing the internal force behaviors acting between supporting bodies (after [67.116])

Fig. 67.41a–d A digital figure climbing a ladder by using whole-body controller with task priority with multiple contacts (after [67.117])

on a rough terrain by supporting a handrail has been performed (Fig. 67.39).

Controlling Whole-Body with Multiple Contacts

The execution of the multicontact motions presented earlier by a humanoid requires the control based on sensor feedback to absorb unexpected disturbance or modeling errors.

Khatib et al. extended their framework of operational space approach that enables a humanoid robot to perform motions that simultaneously meet prioritized objectives in existence of multiple contacts [67.116, 117]. A torque-based approach for the control of internal forces is suggested and integrated into the framework for whole-body prioritized multitasking, thus enabling the unified control of COM maneuvers, operational tasks, and internal-force behavior (Fig. 67.40). Figure 67.41 shows an example of multicontact behavior on a real-time simulator. *Hyon* et al. proposed another approach of passivity-based controller that can

adapt to unknown external forces applied to arbitrary contact points without sensing the contact forces by using a torque-controlled robot [67.122].

Another real-time controller based on linear QP optimization has been proposed for whole-body motion with multiple contacts [67.121, 123]. The motion is constrained by the free-floating whole-body dynamics of the humanoid robot without using a reduced model such as inverted pendulum since the motions we aim at are more general than bipedal walking. The optimization process also incorporates such constraints as nonsliding condition, actuation torque limits, contact forces within friction cones, and avoidance of undesirable self-collisions and collisions with the environment. Taking a target contact stance and also necessary sensory information as its input, the controller can compute feedback control commands to execute the whole-body motion with multiple contacts in real time, on less than 100 Hz control loop. Figure 67.42 shows a simulation result of complex motion of a humanoid entering into a car based on the control method.

67.6 Morphological Communication

Humans evaluate each others' state through body posture and movement. It is quite natural to extend this form of communication to include robots that share our morphology.

67.6.1 Expressive Morphology and Behavior

Humanoids can communicate with people through expressive morphology and behavior. As with people, humanoid robots integrate communicative and noncommunicative functionality. For example, the arms and hands of a robot can reach and grasp, but also point and gesture. Heads for humanoid robots are an especially important example of these overlapping roles, and have had an important impact on humanoid robotics and robotics in general [67.124].

The head of a humanoid robot has two main functions:

- To orient directional sensors as needed for the purposes of perception, while leaving the main body free to meet other constraints such as maintaining balance and gait. Cameras and sometimes microphones are usefully oriented in this way.
- To strike expressive poses, along with the rest of the body. Even if a robot head is not intended to be expressive, it will be interpreted as being so by humans – particularly as a cue to the robot's presumed locus of visual attention. It is also possible to deliberately engineer an approximate *face* that can be an important line of communication with humans (Chap. 72).

Locus of Attention

Eyes can be one of the most expressive components of a humanoid robot. For humans, eye movements are both expressive and important for sensing. Humanoid robots

have the option to factor these two roles by moving eyes that are only for display, and using sensors placed elsewhere. Most humanoid robots, however, use head-mounted servoed cameras that play both expressive and sensory roles. These mechanisms exhibit different degrees of biological realism, for example, the Kismet head captured many of the expressive components of human eye movements, while having a nonhuman-like camera arrangement that simplified some forms of perception (Fig. 67.43).

Many humanoid robots use biologically inspired, foveated vision systems, which provide a wide field of view with low detail, combined with a narrow field of view with high detail (Fig. 67.44). With appropriate control strategies to fixate the narrow field of view on task-salient regions detected in the wide field of view, these robots achieve a practical compromise between resolution and field of view. Additionally, the configuration of the eyes communicates the robot's locus of attention in an intuitive way. Many systems use four cameras, with a narrow- and wide-angle camera for each of the robot's eyes, but some researchers have also used special-purpose space-variant cameras modeled after the space-variant receptor densities in the human eye [67.125].

The eye movements of some humanoids are modeled explicitly after human eye movements. An example of a model of this kind is shown in Fig. 67.45. These

bio-inspired approaches to active vision typically have four types of visual behavior:

Saccades. These are high-velocity movements to fixate a new target or *catch up* with a fast-moving target. From a control point of view, these movements are *ballistic* (at least in humans) – once initiated, they continue without responding to changing stimuli.

Smooth Pursuit. These are movements to continuously track a moving target. They apply at low velocities. These movements respond constantly to visual feedback about the target's location. A fast-moving target may also trigger small saccades.

VOR and OKR. The vestibulo-ocular reflex and optokinetic response work to stabilize the direction of gaze in the presence of movement of the head and body, using inertial and visual information respectively.

Vergence. This movement drives the relative angle of the two eyes so that the same target is centered in both. This only applies to two-eyed systems that have this freedom of motion. For conventional stereo algorithms,

Fig. 67.43 On Kismet, foveal vision was implemented using cameras in the eyes, and peripheral vision used unobtrusive cameras on the head (after [67.124]). This achieved good expression of locus of attention, while simplifying the process of differentiating egomotion from motion of objects (since the head moved less frequently and more slowly than the eyes). This is an example of a partial decoupling of expressive and functional concerns, showing that many different levels of humanoid *fidelity* are possible

Fig. 67.44a–d The heads of humanoid robots come in many forms. A popular arrangement is to have two cameras per eye, as a crude approximation of foveal and peripheral vision in humans. (a) Biomimetic oculomotor control investigated on DB (after [67.126]). (b) Cog's head (after [67.127]). (c) The double-camera arrangement can be arranged in a less-double-barreled appearance (after [67.128]; see Ude et al. [67.128] for more examples and an analysis) ATR; Humanoid head developed by ATR and SARCOS. (d) The Infanoid robot (after [67.129])

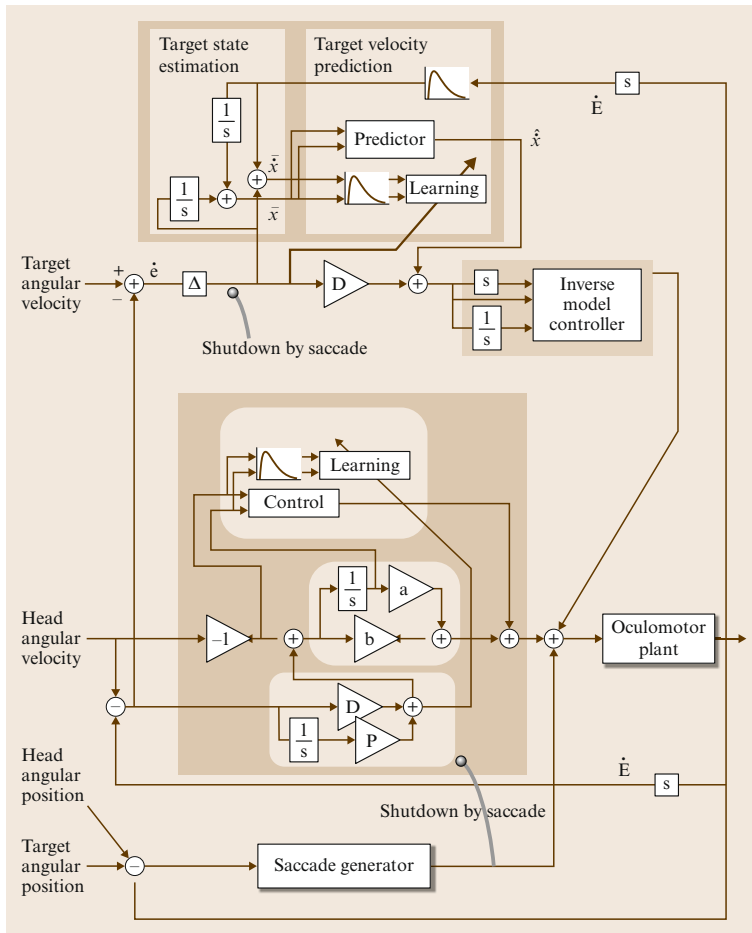

Fig. 67.45 A biomimetic control model (after [67.130]), that integrates saccading, smooth pursuit, the vestibular-ocular reflex (VOR), and the optokinetic response (OKR). Smooth pursuit and VOR/OKR commands are summed, with periodic corrections to errors in position made by saccades

vergence is a disadvantage, since the algorithms are simplest when the cameras remain parallel. Other algorithms are possible, but it is currently quite common not to use vergence.

67.6.2 Interpreting Human Expression

The interpretation of human expression is essential for many forms of natural human communication that could be valuable for humanoid robots.

Posture and Expression

The recognition and interpretation of the location and pose of humans is important, since humanoids are often expected to work in human environments. Algorithms for the following functions have been incorporated in various humanoids:

- Person finding
- Person identification

- Gesture recognition
- Face pose estimation.

ASIMO has used these functions to perform a prototypical reception task as shown in Fig. 67.46. The robot can find and identify a person, then recognize gestures such as *bye-bye*, *come here*, and *stop*, which are utilized for performing reception tasks. In general, such func-

Fig. 67.46 ASIMO recognizing a pointing gesture during a reception task

tions on a humanoid are not yet robust, and are active areas of research.

Speech Recognition

Speech is a natural, hands-free mode of communication between humans, and potentially between robots and humans. Speech recognition is a popular interface utilized for commanding a humanoid, and many off-the-shelf packages are now available. However the use of microphones embedded in the robot is problematic, because general-purpose speech recognition software is usually optimized for utterances captured by a microphone that is close to the speaker. In order to achieve sufficient recognition performance in natural interaction situations between a humanoid and a human new methods for speech recognition are being investigated. These methods compensate for sources of noise, such as the robot's motors and air flow in the environment, by using multiple microphones and multimodal cues [67.131]. However, at the time of writing researchers often circumvent these issues by using a headset, lavalier, or handheld microphones.

Auditory Scene Analysis

In order to attain more-sophisticated human-robot interaction, researchers have been developing methods for computational auditory scene analysis on a humanoid robot. The objective of this research is to understand an arbitrary sound mixture including nonspeech sounds and voiced speech, obtained by microphones embedded in the robot. Beyond speech recognition, this also involves sound-source separation and localization.

As for sound recognition, sound categories such as *coughing*, *laughing*, *beating by hand*, *adult's voice*, and *child's voice* have been shown to be recognizable using maximum-likelihood estimation with Gaussian mixture models. This function has been utilized during interactions between the HRP-2 and a human [67.132].

Multimodal Perception

Sound-source separation can be achieved by beam forming. In order to perform beamforming effectively, sound-source localization is essential. Vision can be utilized for finding the talker within the field of view. Hara et al. used a camera and an eight-channel microphone array embedded in the head of HRP-2, and succeeded in speech recognition in the presence of multiple sound sources by using sound source separation [67.133]. Figure 67.47 shows a scenario in which speech recognition is taking place with television (TV) sound playing in the background.

When integrated with speech recognition, vision can also help resolve the ambiguities of speech. For instance, the ambiguity of demonstrative pronouns such

as *this* or *that* can sometimes be resolved by recognizing pointing gestures. Similarly, the face and gaze direction can be used to realize communication via eye contact, so that the humanoid only replies when a human is looking at it and talking to it [67.132]. Multimodal interaction with these functions has also been demonstrated by HRP-2, as shown in Fig. 67.48.

67.6.3 Physical Interaction and Developmental Robotics

Humanoid robots typically use methods for perception and interaction that are established in fields such as computer vision and dialogue systems. There is also an emerging research field called developmental robotics or epigenetic robotics in which human-like perception and interaction abilities are obtained through physical interaction with the real environments including humans [67.134–136]. In developmental robotics, researchers aim at studying the developmental mechanisms, architectures and constraints that allow life-long and open-ended learning of new skills and new knowledge in embodied machines. Much of the research in this field utilizes humanoid robots, such as the iCub shown in Fig. 67.36. As in human children, learning is expected to be cumulative and of progressively in-

Fig. 67.47 HRP-2 recognizing speech with background noises (TV sound)

Fig. 67.48 HRP-2 recognizing face and gaze direction for communication via eye contact

creasing complexity, and to result from self-exploration of the world in combination with social interaction. The typical methodological approach consists in starting from theories of human development elaborated in fields such as developmental psychology, cognitive science, neuroscience, developmental and evolutionary bi-

ology, and linguistics, then to formalize and implement them in robots. The experimentation of those models in robots allows researchers to confront them with reality, and as a consequence developmental robotics also provides feedback and novel hypothesis on theories of human development.

67.7 Conclusions and Further Reading

Because of the integrative nature of humanoid robotics, this chapter has avoided details and formalisms and liberally cross-referenced other chapters within the handbook that can provide the reader with deeper coverage of many of the areas of robotics on which humanoid robots depend. Additionally, this chapter references work within the humanoid robotics community and related communities.

Humanoid robotics is an enormous endeavor. The emulation of human-level abilities in a human-like robot serves as a grand challenge for robotics, with significant cultural ramifications. The motivations for humanoid robotics are as deep as they are diverse. From the earliest cave drawings, humanity has sought to represent itself. Robotics is one of the most recent mediums for this ongoing fascination. Besides this deep societal motivation, hu-

manoid robots offer unique opportunities for human-robot interaction, and integration into human-centric settings.

Over the last decade, the number of humanoid robots developed for research has grown dramatically, as has the research community. Humanoid robots have already gained a foothold in the marketplace as robots for entertainment and research (e.g., the Robo-One competition and the NAO from Aldebaran). Given the special properties of humanoid robots, they seem likely to further increase in number as their capabilities improve and their costs go down. Robots with human characteristics, and technologies related to humanoid robotics, also appear destined to proliferate. Will human-scale, legged robots with human form become commonplace, as so often imagined by science fiction? Only time will tell.

68. Human Motion Reconstruction

Katsu Yamane, Wataru Takano

This chapter presents a set of techniques for reconstructing and understanding human motions measured using current motion capture technologies. We first review modeling and computation techniques for obtaining motion and force information from human motion data (Sect. 68.2). Here we show that kinematics and dynamics algorithms for articulated rigid bodies can be applied to human motion data processing, with help from models based on knowledge in anatomy and physiology. We then describe methods for analyzing human motions so that robots can segment and categorize different behaviors and use them as the basis for human motion understanding and communication (Sect. 68.3). These methods are based on statistical techniques widely used in linguistics. The two fields share the common goal of converting continuous and noisy signal to discrete symbols, and therefore it is natural to apply similar techniques. Finally, we introduce some application examples of human motion and models ranging from simulated human control to humanoid robot motion synthesis.

68.1 Overview

Human motions are valuable resources for robots as they implicitly represent human strategies for control and planning. They are particularly useful when the control objective is difficult to formulate as a cost function, such as conveying expressions or moving in a particular style. Many researchers have used human motions for teaching new tasks to robots [68.1] and generating robot motions with human-like styles [68.2].

In order to use human motions for robotics applications, we first have to reconstruct the motion from raw measurement from a motion capture system. For this

purpose, we can apply many techniques and algorithms developed in robotics such as kinematics, dynamics, parameter identification, and statistical models. In some applications such as robot learning, reconstructed motion data represented as sequences of joint angles are often not useful. In this case, the motion must be interpreted as higher level representation such as a sequence of behaviors.

This chapter reviews some of the algorithms for reconstructing and interpreting human motions for robotics applications. The next section describes the

kinematic and dynamic computations for human motion reconstruction. As these algorithms were originally developed for robot manipulators, we need substantial adaptation to human body due to its complexity. In Sect. 68.3, we present an overview of statistical approaches for understanding human motions as discrete behaviors, and use them for communication between

humans and robots. The technique presented here has a close relationship to natural language processing that deals with the similar problem of converting continuous signal (sound) to discrete symbols (words). Finally, we review a few examples of using human motions to generate human-like motions on virtual humans as well as humanoid robots.

68.2 Models and Computations

Motion capture refers to measuring motions in the Cartesian space. The subjects are usually humans but animals or robots may also be used. Many motion capture technologies are commercially available with varying costs and capabilities. We will give a brief overview of the most popular motion capture systems: optical and mechanical.

68.2.1 Motion Capture Technology

Optical Motion Capture

Optical motion capture systems are popular thanks to the minimum disruption to motions, although high-end systems can be expensive because of high-resolution, high-speed cameras and elaborate software. Furthermore, offline data cleanup is often necessary to handle occasional occlusion and mislabeling. These systems are widely used in many fields including biomechanics, entertainment, and robotics.

Figure 68.1 shows the principle of optical motion capture. Multiple markers (white circles) are attached to the subjects' body (gray) as *landmarks* to be detected by the cameras surrounding the capture area. The three-dimensional (3-D) marker positions are obtained by computing the intersection of lines connecting the cameras' optical center and the markers on the image plane.

Human whole-body motion capture typically requires more than 40 markers. The markers are usu-

ally spherical and retro-reflective, which means that they reflect the incoming light directly back to the light source. The subject experiences very little disruption during motions because the markers are light and small, although they can be a problem in motions that involve physical contacts with other subjects or the environment.

The capture area is surrounded by three or more cameras with near-ultraviolet light source. Because the markers are retro-reflective, they can be easily detected in the camera images as bright disks by simple image processing with little effect from the lighting condition. The internal and external camera parameters are identified through a system-specific calibration process before each motion capture session.

Human motions are reconstructed in three steps. First, the markers are detected from the camera images. Then the Cartesian positions of the markers can be computed by using the marker positions from multiple cameras. Finally, joint angle data are computed by performing inverse kinematics computation (VIDEO 762). This step will be described in Sect. 68.2.2.

The complexity of the software is due to the three-dimensional (3-D) reconstruction process where it is difficult to identify the correspondence between the markers in multiple images because all markers look identical. Furthermore, some of the markers may be lost due to occlusion and fast motions. In practice, careful marker and camera placement is required to obtain consistent measurements.

Mechanical Motion Capture

Another family of motion capture technology is mechanical, where a mechanical device is attached to the subject's body to directly measure the joint angles. Earlier systems used mechanical linkages consisting of rigid links and joint angle sensors, which were bulky and therefore significantly restricted the subjects' mobility. However, more recent systems use flexible suits with embedded bend sensors that do not cause as much restriction. The suits are equipped with additional inertial sensors to measure the global position.

Fig. 68.1 Principle of optical motion capture

An advantage of this technology is that it can directly measure the joint angles, and therefore is more robust than optical systems. It also allows unbounded capture area, possibly in outdoor environments. On the other hand, the inertial sensors used for measuring the global motion of the body may suffer from drifts that result in inaccurate global position measurements. Drifts are usually corrected assuming that at least one of the foot segments is fixed to the environment, but this is not the case in motions involving flights.

Future of Motion Capture

Development of markerless, realtime, and low-cost motion capture systems is an active research area in both academia and industry. In fact, several commercial products with some of those features are becoming available.

For example, the OpenStage system [68.3] from Organic Motion realizes realtime markerless motion capture. Kinect [68.4] has been developed for gaming interface but it can potentially be used as a low-cost, realtime motion capture system. Some researchers are working on even more challenging motion capture techniques, such as markerless motion capture using monocular vision [68.5].

68.2.2 Skeleton Model and Computation

Once motion capture data are obtained, we can analyze the data by computing the joint angles and torques, provided that kinematics and dynamics models of the subject are available. While a number of algorithms have been developed for motion analysis and simulation of robots, applying these algorithms to the human body is not straightforward.

The human body is much more complex than most mechanical systems. It consists of a number of elements such as bones, muscles, organs, and skin, most of which are deformable and difficult to model themselves. Many joints are also difficult to model and simulate because of the complex constraints. For example, the center of rotation of the shoulder joint moves along with the joint movement. The knee and elbow joints are constrained by rolling contacts and ligaments between bones.

In practice, therefore, it is unrealistic to model all the details due to computational complexity, and the human body is typically approximated by articulated rigid body models familiar to the robotics community. We can then apply the kinematics and dynamics algorithms for mechanical systems as described in this subsection. Figure 68.2 shows an example of detailed human skeleton model [68.6], which consists of 155 degrees of freedom (DOF) excluding the fingers.

Fig. 68.2 Detailed human skeleton model

Even if we use simplified skeleton models, there is still an issue of obtaining accurate model parameters. As mentioned above, many joints do not have a fixed axis as in mechanical joints, which means that the kinematic parameters such as link length may not be constant as in mechanical systems. It is also difficult to estimate the inertial parameters because we cannot directly measure the individual link parameters, and because the human body is flexible and some of the soft tissue would move between links. We will discuss the parameter identification issue in Sect. 68.2.4.

Kinematics

Inverse and forward kinematics computations are used to analyze the kinematic quantities of measured motions such as positions, velocities, and accelerations of the links.

Inverse kinematics computation is critical to data obtained by optical motion capture because we have to convert the marker positions to skeleton joint angles. Typical inverse kinematics problem in robotics (Chap. 2) is to compute the joint angles given the

end-effector position and/or orientation. Inverse kinematics for motion capture data processing needs a slightly different problem setting because many markers are attached throughout the body, often resulting in an over-constrained system. Furthermore, measured marker positions would not perfectly fit an articulated rigid body model because human kinematics parameters may change during the motion, as discussed above.

A simple method for computing the joint angles, often used as the default method in commercial optical motion capture systems, is to first compute the joint centers by interpolating the positions of a few strategically placed markers, and then computing the joint angles from the joint centers. The advantage of this method is that it is easily customizable by, for example, simple scripts and therefore suitable for commercial systems.

Another method is to apply numerical optimization. For example, the cost function can be the sum of squared distances between the marker positions from the measurement and those computed by the kinematics model. Another approach is to *drive* the model toward the measured marker positions [68.7]. In either case, the resulting joint angle will evenly distribute the error caused by measurement error and model inaccuracy to all markers.

Figure 68.3 shows an example of inverse kinematics using a skeleton model.

Forward kinematics is performed to obtain the Cartesian positions, velocities, and accelerations of the links from the corresponding joint variables. These quantities are often used for the dynamics computation later.

Dynamics

Similarly to kinematics computation, we can consider both inverse and forward dynamics.

Fig. 68.3 Inverse kinematics computation example

Inverse dynamics computes the joint torques and possibly contact forces required to perform the measured motion. Any algorithm for inverse dynamics computation of articulated rigid bodies, such as the Newton–Euler formulation [68.8], can be applied. Chapter 3 gives the details on dynamics algorithms for general kinematic chains.

A major difference from manipulator inverse dynamics is that the human body is a floating-base system where the root joint can move freely in the six-dimensional (6-D) space but is not actuated. Generic inverse dynamics algorithms for manipulators give the 6-D force and torque for the root joint but they are not actually available. The equivalent force must be supplied instead by the contact forces, which have to be explicitly considered because they affect the joint torques.

The equation of motion of an n -DOF articulated rigid body system is written as

$$\tau_G = \mathbf{M}(\theta) \ddot{\theta} + \mathbf{c}(\theta, \dot{\theta}) + \mathbf{g}(\theta), \quad (68.1)$$

where $\tau_G \in \mathbb{R}^n$ is the generalized force, $\theta \in \mathbb{R}^n$ is the generalized coordinate, $\mathbf{M} \in \mathbb{R}^{n \times n}$ is the joint-space inertia matrix, $\mathbf{c} \in \mathbb{R}^n$ represents the centrifugal and Coriolis forces, and $\mathbf{g} \in \mathbb{R}^n$ is the gravitational force. In human body models subject to m contact constraints, τ_G is computed from active joint torques $\tau \in \mathbb{R}^{n-6}$ and contact forces $\mathbf{f}_c \in \mathbb{R}^m$ as

$$\tau_G = \mathbf{S}^T \tau + \mathbf{J}_c^T \mathbf{f}_c, \quad (68.2)$$

where $\mathbf{J}_c \in \mathbb{R}^{m \times n}$ is the Jacobian matrix of the contact constraints and $\mathbf{S}^T \in \mathbb{R}^{n \times (n-6)}$ is the matrix that converts the active joint torques to generalized forces. Without losing generality, we assume that the root joint corresponds to the first six elements of the generalized coordinate. Then \mathbf{S}^T takes the form

$$\mathbf{S}^T = \begin{pmatrix} \mathbf{O}_{6 \times (n-6)} \\ \mathbf{I}_{(n-6) \times (n-6)} \end{pmatrix} \quad (68.3)$$

where \mathbf{O}_* and \mathbf{I}_* are the zero and identity matrices of the sizes given by the subscripts.

The number of constraints m changes depending on the contact condition. If, for example, both feet are in flat contact with the ground, m would be 12 because the position and orientation of each foot are constrained.

Equations (68.2) and (68.3) indicate that only \mathbf{f}_c contributes to the first six elements of τ_G . This property corresponds to the well-known fact that the whole-body momentum can be changed only by applying external forces such as contact forces. We can utilize this fact to compute \mathbf{f}_c independently of the joint torques [68.6].

We can then compute the joint torques using the bottom $(n - 6)$ equations of (68.2).

Forward dynamics is used for dynamics simulation. The simulation in this context usually involves a set of controllers that attempts to make the human model track the measured motion. This computation is often performed to simulate the effects of external disturbances and physical disabilities. However, developing controller for human body simulation is very difficult because the root joint is not actuated and the contact forces are subject to unilateral constraints. Although this topic is extensively discussed in humanoid robotics, graphics, and biomechanics, there is no consensus on how to build general controllers for human models.

68.2.3 Musculoskeletal Model and Computation

Motion analysis based on skeleton models is not sufficient for applications that require anatomical information such as muscle lengths and tensions. In biomechanics, for example, researchers are often interested in computing the muscle tensions required to perform a motion. Also in robotics, many muscle-like actuators are developed and used to design more human-like robotic systems.

Musculoskeletal models are used for motion analysis involving muscles. In addition to a skeleton model discussed in the previous section, a musculoskeletal model includes a musculotendon network model that describes where the muscles are attached to and how

they are routed around the bones. Similarly to skeleton models, musculotendon network models include a number of simplifications due to the complexity of the real human body. A muscle is usually modeled as a line segment that produces a uniform tensile force. Interactions of muscles with bones and skin are not usually modeled except for some of the major muscle–bone interactions.

Apart from these simplifications, the force interaction between the muscles and bones are described as accurately as possible. A simple muscle–tendon pair connects two bones and produces a torque at the joint between them (Fig. 68.4a). More complex muscles may pass through one or more points fixed on the bone surface (Fig. 68.4b), or may have branches and therefore connects three or more bones. Wide muscles, such as pennate muscles, are modeled by several parallel muscles.

Figure 68.5 shows a detailed musculoskeletal model consisting of 955 muscles [68.6].

Kinematics computation on a musculoskeletal model gives the muscle lengths. The length and its velocity may then be used for various analysis. For example, we can use Hill–Stroeve muscle model [68.9, 10] to compute the maximum muscle tension.

The active joint torques τ are now produced by muscle tensions f_m . Applying d’Alembert’s principle, we can derive the relationship between τ and f_m as

$$\tau = J_m^T f_m, \quad (68.4)$$

where J_m is the Jacobian matrix of the muscle lengths with respect to the generalized coordinates.

Fig. 68.4a,b Examples of muscle models; (a) simple wire connecting two bones, (b) muscle with via point

Fig. 68.5 A detailed musculoskeletal model

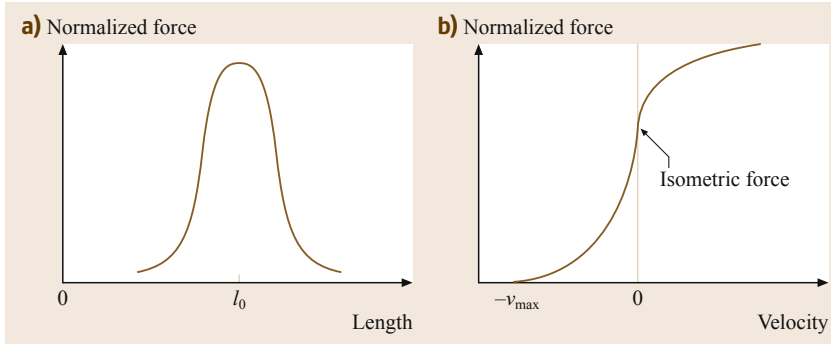

Fig. 68.6a,b Relationship between maximum muscle tension and muscle fiber length. **(a)** Length–tension relationship, **(b)** velocity–tension relationship

The inverse dynamics computation for musculoskeletal models is summarized as follows:

1. Compute the joint angles, velocities, and accelerations of the motion capture data.
2. Compute the joint torques τ of the skeleton model.
3. Map the joint torques to muscle tensions using (68.4) (VIDEO 763).

Because most musculoskeletal models contain more muscles than the skeleton DOF, the final step does not have a unique solution. The muscle tensions also have to be constrained to be tensile. A common approach for this problem is to apply numerical optimization techniques [68.6, 11]. However, actual muscle tensions may not be optimal because of the phenomena called co-contraction, where antagonistic muscles are activated at the same time. Such effect can be incorporated by measuring the muscle activity through electromyography (EMG) and consider the data in optimization [68.12].

Another method for computing muscle tensions is to utilize physiological muscle models. The most commonly used model was originally proposed by Hill [68.9] and later formulated by Stroeve [68.10].

Muscle tension f is characterized by three components: muscle activity a , muscle length l , and change of muscle length \dot{l} as follows:

$$f = a F_l(l) F_v(\dot{l}) F_{max}, \quad (68.5)$$

where F_{max} is the muscle-specific maximum voluntary force, $F_l(*)$ and $F_v(*)$ are the functions that represent length–tension and velocity–tension relationship respectively (Fig. 68.6). The muscle activity a changes according to the following differential equation,

$$\dot{a} = \frac{u - a}{T}, \quad (68.6)$$

where T is a time constant and u is the normalized input from the motor neuron which can be measured by EMG.

68.2.4 Model Identification

Obtaining accurate human model parameters is difficult but very important for accurate motion and force estimation. For robots, we can build a model based on CAD (computer-aided design) models or even measurements of the individual link mass, but both are impossible for humans. On the other hand, personalized models are important to make the analysis results useful for individuals.

Identification of Kinematic Parameters

In human motion analysis, the set of joints constructing a human model is usually given. Kinematic parameters include distance between joints and direction of the joint axes.

We can apply some of the kinematic parameter identification techniques for robots [68.13] using motion capture to provide the data necessary for identification. Another approach is to use a human dimension database [68.14] and use a few measurements from the subject to estimate the rest.

Identification of Inertial Parameters

Conventional methods for manipulator inertia parameter identification (Chap. 6) use joint torque data, and therefore cannot be applied to the human body.

However, Ayusawa et al. [68.15] proved that contact force data give enough information to estimate the same set of parameters for floating-base models. As shown in Chap. 6, the generalized force τ_{Gi} required to perform a given motion described by the generalized coordinates θ_i , velocities $\dot{\theta}_i$, and accelerations $\ddot{\theta}_i$ is written as a linear equation of the identifiable inertial parameters p as

$$\mathbf{I}_i(\theta_i, \dot{\theta}_i, \ddot{\theta}_i) p = \tau_{Gi}. \quad (68.7)$$

We can obtain a number of these samples from motion capture data. In manipulators with joint torque sensors, all elements of \mathbf{I} and τ_G are available and therefore it is trivial to solve (68.7).

As shown in (68.2), the generalized forces for human body models are produced by active joint torques and contact forces. From (68.3), (68.7) can be divided into the first six rows and the remaining $(n - 6)$ rows as

$$\mathbf{I}_{ji}(\boldsymbol{\theta}_i, \dot{\boldsymbol{\theta}}_i, \ddot{\boldsymbol{\theta}}_i)\mathbf{p} = \mathbf{J}_{cji}^T \mathbf{f}_{ci}, \quad (68.8)$$

$$\mathbf{I}_{ai}(\boldsymbol{\theta}_i, \dot{\boldsymbol{\theta}}_i, \ddot{\boldsymbol{\theta}}_i)\mathbf{p} = \boldsymbol{\tau}_i + \mathbf{J}_{caif}^T \mathbf{f}_{ci}. \quad (68.9)$$

For human body, joint torque data $\boldsymbol{\tau}_i$ are not available. However, we can obtain the contact force data from force sensors embedded in the floor. In this case, we have all the information in (68.8). Ayusawa et al. [68.15] proved that this equation is enough for identifying the same set of parameters as using the full set of (68.7).

68.3 Reconstruction for Understanding

Human motion data can be used for motion and task learning for humanoid robots, as represented by imitation learning or learning by demonstration [68.1].

68.3.1 Segmentation of Human Motion

Human motion data are converted to a sequence of configurations, such as joint angles or link positions over the whole of the robot's body, and the sequence is encoded into a set of model parameters as the motion primitive. This encoding should follow the motion segmentation; a chunk of motion should be obtained by finding the frames where the motion starts and terminates in the seamless motion data. Manually selected motion segments are intuitive, reliable, and easily assigned their relevant motion labels. However, manual segmentation is limited by its lack of scalability for the large numbers of human motions required for training. Human motion should be segmented so that a humanoid robot can observe human actions and incrementally memorize the motion primitives by segmenting and encoding unknown motions.

In the supervised segmentation method, the relation between each motion frame and its boundary score from the training dataset is learned, and the boundary in the motion observation is identified. For the training dataset, human subjects have to detect the motion boundaries. Supervised segmentation has the same drawback in scalability to large motion datasets as manual segmentation.

There are studies of unsupervised segmentation based on various methods: stopped moment, motion clustering, and motion prediction. Motion segmentation based on the stopped moments is very simple. This segmentation assumes that a motion pattern transits to another motion via the stopped moment. The simplest strategy only has to find a pose when either joint stops as a boundary candidate. The extensive approach approximates a temporal sequence of the boundary candidates by a periodic function as a reference for the motion boundaries. These methods may work for rhythmic movements, such as dance, but it is not clear

whether they would be useful for segmenting daily human actions [68.16, 17].

Stochastic graphical models, typified by hidden Markov models (HMM), are used to model the stream of motion data [68.18]. An optimal node in the graphical model that is the most likely to generate the current motion observation can be calculated. The observations classified into the same node consequently are considered to be the same motion. In other words, the transition between two nodes corresponds to the boundary of the motions [68.19].

In natural language processing, word segmentation is critical, especially for speech recognition, in which words must be selected from a stream of phonemes. Predictability strategy hypothesizes that it is difficult to predict the character at the beginning of the word. A recurrent network based on this strategy has been applied to the segmentation of words [68.20]. The network learns the sequence of characters, and consequently predicts the character from its preceding one. This predictor detects a boundary where the error between the predicted and actual character becomes large, and subsequently selects words. Similar to this approach, during motion learning motion is converted to a sequence of short movements, each of which is represented by a binary vector equivalent to a word, and this sequence is trained as the correlation matrix. This matrix can be easily used to predict the short movement by multiplying this matrix by the vector of the preceding movement [68.21]. Movements with a large prediction uncertainty can be detected as the motion boundary.

68.3.2 Categorization of Human Motion

Human motion data is encoded into a set of parameters in the dynamical systems [68.22, 23] or stochastic models [68.24, 25]. The dynamical system representing state transitions by nonlinear differential equations is a popular way to encode human motions and subsequently synthesize robot motion adapted to various environments. The dynamics in the human motions is

defined as a vector field, and each motion pattern is expressed by a closed curve in this field, which is constructed so as to attract robot's motion to the reference motion [68.26]. This attractor field will stabilize the robot's motion even when the robot is perturbed by the external environment. A popular approach based on the dynamical system is a framework of the dynamic movement primitives (DMPs) [68.27]. This framework learns a single trajectory by using a spring-damping model including a forcing term which makes it easy to control a robot motion reaching a goal configuration. This framework has been extended to learn multiple human motions such that the robot can perform various motions and demonstrate the highly scalable nature [68.28]. These dynamical systems mainly focus on synthesize and control robot motions adaptively to the environment. While they can predict motions and classify the observation into its specific motion category, but they are not directly used for motion classification. Another popular approach based on the dynamical system is a recurrent neural network (RNN). The RNN generates the human posture following the input current one, and is optimized such that error between the generated posture and measured one can be minimized. The resultant RNN can be useful for the motion predictor. The RNN has been extended to a modified structure with a layer of the small number of parametric biases, into which the dynamics in the human motion can be encoded [68.29]. This structure has an advantage of not only generating motions from perception, but also recognize the perception as a category defined by these biases. Due to the complexity of the model structure, it is difficult to tune the parameters from a large number of training data.

Stochastic framework, typified by HMMs, are widely used for categorization of human motions. A compact notation $\lambda = \{\Pi, \mathbf{A}, \mathbf{B}\}$ represents an HMM. Π is a set of initial node probabilities $\Pi = \{\pi_i\}$, \mathbf{A} is a transition matrix $\mathbf{A} = \{a_{ij}\}$ whose entries a_{ij} is the probability of transitioning from the i -th node to the j -th node, and \mathbf{B} is a set of output distributions $\mathbf{B} = \{b_i(\theta)\}$. Figure 68.7 shows the overview of the HMM. Human motion is expressed by a sequence of joint angles or link positions, $\mathbf{x} = \{\theta_1, \theta_2, \dots, \theta_T\}$. The parameters of the HMM are optimized by Baum–Welch algorithm, which is one of expectation maximization algorithms, such that the likelihood $P(\mathbf{x}|\lambda)$ of the human motion \mathbf{x} being generated by its relevant HMM λ is maximized [68.30]. The HMM represents spatiotemporal features of the human motions, and is hereafter referred to as motion primitive.

Human motion \mathbf{x} can be classified into a motion category represented by the motion primitive. The classification finds an HMM $\lambda_{\mathcal{R}}$ which is the most likely to

Fig. 68.7 The overview of an HMM. An HMM is the graphical model. A node extracts the spatio feature and an edge extract the temporal feature

generate the human motion as follows

$$\lambda_{\mathcal{R}} = \arg \max_{\lambda} P(\mathbf{x}|\lambda). \quad (68.10)$$

The likelihood $P(\mathbf{x}|\lambda)$ can be efficiently computed in the recursive manner by the forward algorithm

$$\alpha_t(j) = \sum_i \alpha_{t-1}(i) a_{ij} b_j(\theta_t), \quad (68.11)$$

$$P(\mathbf{x}|\lambda) = \sum_i \alpha_T(i), \quad (68.12)$$

where $\alpha_t(j)$ is the probability of generating a sequence $\{\theta_1, \theta_2, \dots, \theta_t\}$ and staying at the j -th node at the time t .

68.3.3 Temporal Sequence of Human Motion

The representations of not only motion segments but also the temporal sequence of them are important for the robots to accurately understand human actions. *Motion graph* is the popular approach to represent the transition between human postures [68.31]. It is possible to transfer between two postures that are similar to one another. This framework creates the edges among the human postures based on their spatial similarities.

The motion segmentation and motion categorization can be extended to the representation of temporal sequence of human motions. Human motion is expressed by a series of motion segments $\{\dots, \mathbf{x}(k-1), \mathbf{x}(k), \mathbf{x}(k+1), \dots\}$ by the segmentation technique, and the series of motion segments is converted to a temporal series of motion primitives $\{\dots, \lambda(k-1), \lambda(k), \lambda(k+1), \dots\}$ by the motion categorization technique. The transition structure of the motion primitives can be extracted by deriving a motion N -gram model from the series of motion primitives. The

motion N -gram model assumes that the motion primitive depends only on its $N-1$ pieces of the motion primitives. The simplest structure is the motion bigram (2-gram) model. The probability of transitioning from the motion λ_i to the motion λ_j can be estimated as

$$P(\lambda_i|\lambda_j) = \frac{\sum_k C[\lambda(k-1) = \lambda_j, \lambda(k) = \lambda_i]}{\sum_k C[\lambda(k) = \lambda_j]}, \quad (68.13)$$

where $C(\lambda)$ is the frequency of the motion λ appearing in the observation of human motions, and this transition probability maximizes the probability of the observation being generated by the motion bigram model.

This transition structure can be used for several applications such as editing animation character, detecting abnormal actions, or predicting human actions [68.32]. In the case of the action prediction, current human motion is classified into the specific motion $\lambda(0)$. The sequence of the motions $\lambda = \{\lambda(1), \lambda(2), \lambda(K)\}$, which is the most likely to be generated by the motion bigram model, can be searched for by Dijkstra's algorithm

$$\begin{aligned} \lambda_p = \arg \max_{\lambda} & P[\lambda(K)|\lambda(K-1)] \\ & \times P[\lambda(K-1)|\lambda(K-2)] \cdots P[\lambda(1)|\lambda(0)]. \end{aligned} \quad (68.14)$$

The selected sequence of motions is considered to be motions predicted from the current motion (VIDEO 764).

68.3.4 Linguistic Interpretation of Human Motion

Integration of the human motions with the natural language leads to not only understanding the human motions in the form of linguistic expressions but also generating robot's motions from the queries of language commands. A framework of RNN with parametric bias has been applied to the integration of the motions and language. One RNN represents the dynamics in the motions, and the other RNN represents the dynamics of language, more specifically sequences of words. The parametric biases shared by these two RNNs join together RNNs [68.33]. Given sentences, the parametric biases for the sentences are estimated in the RNN for the language, the RNN for the motion generates motions using the parametric biases derived from the language RNN. The robot can generate the motions corresponding to the sentences. This conversion from the language to the motions is reversed, and it allows for the conversion from motions to their descriptive sentences [68.34].

Another integration of the human motions with language is stochastic approach. Human action is represented as a sequence of motion primitives $\{\lambda(1), \lambda(2), \dots, \lambda(k)\}$. A sequence of verbs $\omega(1), \omega(2), \dots, \omega(l)$ is also manually assigned to the same human action, where $\omega(i)$ is the verb assigned to the manually segmented motion at the i -th position. The problem of extracting the references between the human motions and the verbs can be considered as a translation problem since the human motion is expressed by a sequence of symbols (Fig. 68.8). The IBM translation model has been widely used in the natural language processing [68.35], and can be applied to integrating the human motions with their relevant verbs [68.36]. This translation model consists of translation probability $t(\lambda|\omega)$ of the motion λ being generated by the verb ω , and alignment probability $a(i|j, l, k)$ that the i -th position in a sequence of the verbs can align to the j -th position in a sequence of the motions. These parameters are optimized such that the following probability that the sequence of verbs generates the sequence of motions is maximized by the expectation-maximization (EM) algorithm.

$$\Phi = P(\lambda(1), \lambda(2), \dots, \lambda(k) | \omega(1), \omega(2), \dots, \omega(l)). \quad (68.15)$$

Additionally, the verb bigram model extracts the transition between two verbs as the verb transition probability $P(\omega_i|\omega_j)$ from the sequences of verbs attached to the human motions. A sequence of verbs $\omega = \{\omega(1), \dots, \omega(l)\}$ which is the most likely to describe the human motion is

$$\omega_R = \arg \max_{\omega} P(\omega|\lambda) = \arg \max_{\omega} P(\lambda|\omega)P(\omega). \quad (68.16)$$

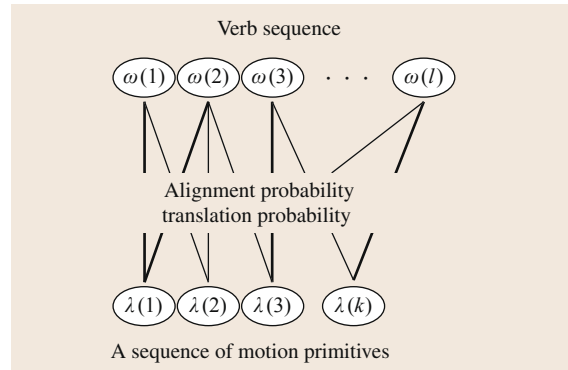

Fig. 68.8 Mapping between sequences of verbs and motion primitives

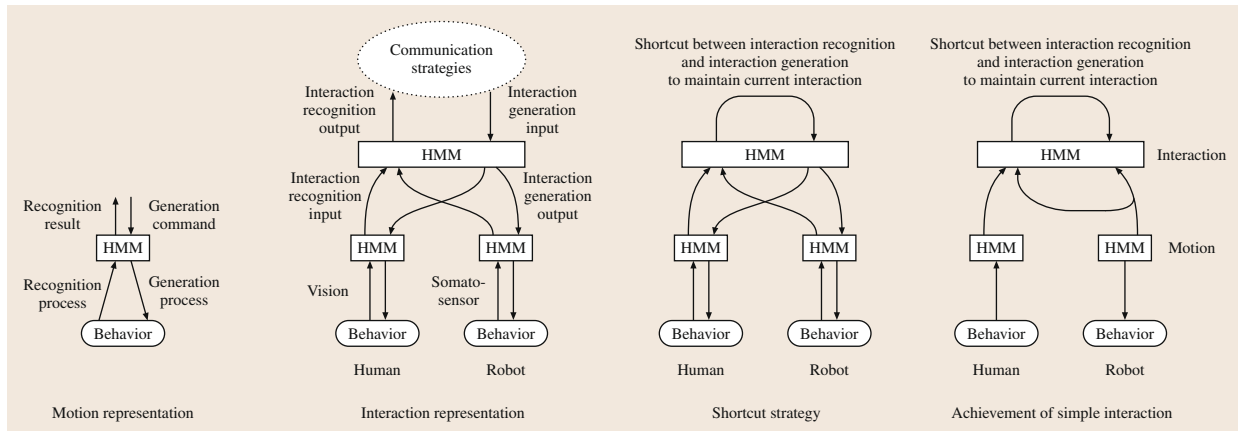

Fig. 68.9 Modeling of the behavioral interaction

$P(\lambda|\omega)$ can be computed using the translation probability and alignment probability, and $P(\omega)$ can be computed using the verb transition probability. The human motion is interpreted as the resultant verb sequence ω_R . This framework has been extended to handling not only verbs but also nouns, adverbs such that human motion can be converted to the descriptive sentences [68.37] (VIDEO 766).

68.3.5 Theory of Communication

HMMs has been extended to hierarchical HMMs (HHMM) or coupled HMMs (CHMM) to represent complicated spatiotemporal features. Statistical model is embedded into each node of the HMM in HHMM while commonly used HMM has an Gaussian distribution function in the node [68.38]. CHMM, in which multiple HMMs interact, is a method for representing mutual dependence between two such as a human and a robot, or a motion and a manipulated object. These approaches may be applied to the interaction that requires the complex representation [68.39]. However, the large number of parameters in these frameworks limits their application, and it is difficult to use these frameworks for human–robot interaction.

One efficient approach to using the representation of human motions as HMM is to design hierarchy for motion primitives and interaction primitives. HMMs representing human whole body motions can be useful to recognize motion observation. The HMMs can be reused to generate human-like motions for humanoid robot. A node is sampled according to the node transition probabilities, and a configuration is sampled according to the output probabilities on the selected node. The generation of the robot motion by the sampling manner can be done in the same framework. It is fundamental for the humanoid robot not only to rec-

ognize human motions but also to generate human-like motions, and this framework has been applied to the interaction between a human and a humanoid robot as shown in Fig. 68.9.

The behavioral interaction is defined by the exchange of the motion primitives between the two [68.37]. Observation of two interacting humans is converted to a sequence of pairs of motion primitives by recognizing their motions using the HMMs. HMMs in the higher level represent these interactions. These HMMs are more abstract analogy of representation of the motions, and useful for recognition and generation of the interaction patterns. A hypothesis is then introduced for the simple commutation, more specifically the communication is established by recognizing the relationship of the two and subsequently maintaining it.

The two recognition output of the human and robot using the HMMs in the lower level becomes the input

Fig. 68.10 Human–robot interaction realized by a symbolical hierarchical communication model

of the HMMs in the higher level, and the interaction can be recognized as a higher HMM. The current node can also be estimated in the selected higher HMM. The generation output from this node are a pair of two motion primitives for the human and robot, and they become the input of the lower HMMs. One motion primitive for the human becomes the prediction of human behavior, and another motion primitive for the robot becomes the command for the motion generation. The recognition and generation by the higher HMMs imply the

estimated state of the interaction and the control strategy for the interaction, respectively. The importance for the naturally drifting interaction is to represent the process of the control strategy based on the estimated interaction state as a shortcut between the recognition and generation [68.40]. The experiment of interaction between the human and robot in a virtual world demonstrated its validity as shown in Fig. 68.10, and is further applied to the human–robot interaction with compliant physical contacts [68.41].

68.4 Reconstruction for Robots

This section reviews some examples of synthesizing human-like motions of robots or virtual humans based on human motions and/or physiological model.

68.4.1 Reconstruction for Virtual Humans

Instead of using inverse kinematics as described in Sect. 68.2.2, Demerican et al. [68.42] developed a method for reconstructing human motions by directly tracking marker trajectories with a physically simulated skeleton model. Figure 68.11 shows the set of markers tracked as well as the skeleton model used in the simulation. Examples of measured and simulated marker trajectories are shown in Fig. 68.12, which demonstrates the smoothness of the reconstructed human motions.

68.4.2 Controller Optimization from Physiological Model

Recorded human motion is an outcome of the human motor control. Instead of using the outcome, i. e., the

motion, Wang et al. [68.44] optimized controllers based on physiological human model that includes eight major leg muscles, including both uniarticular (drive single joint) and biarticular (drive two joints) (Fig. 68.13). The method optimizes the controller parameters based on simulation considering the physiological muscle properties [68.9]. The results demonstrate good match with human measurements in terms of both joint trajectories and torques.

68.4.3 Reconstruction for Physical Robots

Tracking human motions with a physical humanoid robot is not as straightforward as it may appear even if the robot has human-like body topology, due to various differences between the human and robot bodies.

First, there is always some difference in the kinematic properties such as dimensions and proportion. In manipulation, for example, simply copying the joint angles will not result in the same hand positions if the upper and lower arm lengths are different.

Fig. 68.11a,b Marker set and skeletal model used in (after [68.42]).
(a) Motion capture data. (b) Skeleton model in simulation and active interfaces (SAI) (after [68.43])

Fig.68.12a,b Joint angles computed from direct marker tracking (after [68.42]). (a) Right arm joint angles. (b) Left arm joint angles

Fig.68.13a-c The musculoskeletal model used in [68.44] (a) skeleton and muscles (red lines), (b) five uniarticular muscles, and (c) three biarticular muscles

The kinematic difference comes not only from different dimensions, but also from flexibility of the human body that is difficult to replicate with mechanical systems. For example, the human spine has much more degrees of freedom than the torso of typical humanoid robots.

Secondly, robot hardware is generally much more restrictive in terms of joint motion range as well as velocity, acceleration, and torque limits. As a result,

robots cannot always perform the same range of motion as humans. We would therefore have to modify the original motions such that they are within the hardware limits.

Finally, the inertial properties such as mass, inertia, and center of mass locations are different. In motions that involve balancing, the different inertial properties may make the motion unbalanced and cause a fall.

While motion capture data have been frequently applied to virtual human characters in simulated environments [68.45–47], much less work has been done on directly controlling humanoid robots with human motion capture data. *Nakaoka et al.* [68.2] divided captured dancing motion into multiple tasks and optimized each task to be feasible for the robot dynamics. *Miura et al.* [68.48] computed feasible center of mass trajectory based on the center of pressure trajectory determined from the footsteps in the motion data, and then computed the joint motions by inverse kinematics.

Ott et al. [68.49] and *Yamane and Hodgins* [68.50, 51], on the other hand, combined online balance control and tracking control to address the problem of different dynamics. Figure 68.14 depicts some snapshots from the hardware experiment of tracking a human motion capture sequence with a floating-base humanoid robot [68.51] ([VIDEO 765](#)).

69. Physical Human–Robot Interaction

Sami Haddadin, Elizabeth Croft

Over the last two decades, the foundations for physical human–robot interaction (pHRI) have evolved from successful developments in mechatronics, control, and planning, leading toward safer lightweight robot designs and interaction control schemes that advance beyond the current capacities of existing high-payload and high-precision position-controlled industrial robots. Based on their ability to sense physical interaction, render compliant behavior along the robot structure, plan motions that respect human preferences, and generate interaction plans for collaboration and coaction with humans, these novel robots have opened up novel and unforeseen application domains, and have advanced the field of human safety in robotics.

This chapter gives an overview on the state of the art in pHRI. First, the advances in human safety are outlined, addressing topics in human injury analysis in robotics and safety standards for pHRI. Then, the foundations of human-friendly robot design, including the development of lightweight and intrinsically flexible force/torque-controlled machines together with the required perception abilities for interaction are introduced. Subsequently, motion-planning techniques for human environments, including the domains of biomechanically safe, risk-metric-based, human-aware planning are covered. Finally, the rather recent problem of interaction planning is summarized, including the issues of collaborative action planning, the definition of the interaction planning problem, and an introduction to robot reflexes and reactive control architecture for pHRI.

69.1 Classification

Robotics is currently undergoing a fundamental paradigm shift, both in research and real-world applications. Classically, it was dominated for the last decades by possibly dangerous position-controlled rigid robots carrying out typical automation tasks, such as positioning and path tracking in various applications. Recently, a new generation of mechatronic robots has appeared on the landscape, including novel concepts in general robot design within the soft-robotics context. This trend brings us closer to the long-term goal of safe, seamless physical human–robot interaction (pHRI) in the real domestic and professional world (Fig. 69.1).

Recent advances in physical human–robot interaction have shown the potential and feasibility of robot systems for active and safe workspace sharing and collaboration with humans. The fundamental breakthrough was the human-centered design of robot mechanics and control (soft-robotics), which also induced the novel research stream of intrinsically elastic robots (series elastic actuators (SEA) or its generalization variable impedance actuators (VIA)). By considering the physical contact of the human and the robot in the design phase, possible injuries due to unintentional contacts can be considerably mitigated. Furthermore, taking into account the human's intention and preferences will en-

able the realization of human-friendly motions and interaction behavior. Some of the most advanced systems that were developed are now entering into industrial markets. These technologies serve both industrial and service-oriented domains. Possible future applications of these novel devices developed for close interaction with humans are depicted in Fig. 69.2. They range from industrial coworkers and mobile servants over robots in the professional service sector, assistive devices for physically challenged individuals, to service robots for the support of general household activities. All of these applications share the common requirement of close, safe, and dependable physical interaction between human and robot in a shared workspace. Therefore, such robots need to be carefully designed for human friendliness. That is, they have to be able to safely sense, reason, learn, and act in a partially unknown world inhabited by humans. In turn, this set of requirements necessitates the design of novel solutions in various theoretical and technological developments. In contrast to the classical modular view on robotics technology, and the role humans play in this, a fundamental paradigm shift in robot development has to be pursued. While encompassing safety issues based on biomechanical human injury analysis as well as on the kinesiological biomechanics

Fig. 69.1 The current paradigm shift in robotics induced by new target domains and robots toward the vision of close human–robot coexistence (courtesy of Keller und Knappich Augsburg (KUKA), Deutsches Zentrum für Luft- und Raumfahrt (DLR), ABB, Rethink Robotics)

Fig. 69.2a–f Application examples for pHRI, ranging from shop floor logistics and manipulation (a,b), over professional service robots and assistive devices for the disabled (c,d), to service robots in domestic applications (e,f)

of human movements, human-friendly hardware design and interaction control strategies, learning, perceptive, and cognitive key components have to be developed and validated. These need to enable robots to track, understand, and predict human motions in real time in a weakly structured dynamic environment. Apart from developing the capabilities for interactive autonomy including self-improvement, human safety and physical interaction have to be embedded at the cognitive decisional level as well. This will enable the robots to react or physically interact with humans in a safe and autonomous way. Biomechanical knowledge, neuromechanical insights, and biologically motivated variable compliance actuators can be used to design manipulation/interaction systems of varying complexity close to human properties and performance. Further fundamental insights into novel designs of VIAs for an improved torque/mass ratio and energy efficiency with new control methods to exploit the stiffness and damping properties are required.

Planning and adapting motions and tasks of such complex systems in real-time require new concepts, including tight coupling of control, planning, and learning, which will lead to reactive behaviors capable of self-improvement. Moreover, self-explaining interaction and communication frameworks need to be developed to enhance the system usability and interpretability for humans. These should, for example, communicate whether a situation is safe or dangerous using not only verbal, but also nonverbal communi-

cation cues, such as gestures and emotional feedback. Finally, the dependability of all system components and algorithms is a major issue, the systematic treatment of which is of particular importance for subsequent industrial commercialization of the technology and also for the commercial domestic use of robots in everyday environments. Thus, the foreseeable breakthrough of the next generation of robotic systems in flexible automation in both small and medium enterprises (SMEs) and global market companies depends primarily on the pHRI development over the next years. Robotic assistance in manual processes that advantageously partner human and robot workers has an enormous unexplored potential to amplify productively in processes that previously could not be automated due to technological, cost, or efficiency reasons. Furthermore, very promising application domains of the technology are in the professional service sector (e.g., hospital support systems) and in the logistics domain (food logistics and quality inspection), which are so far to a large extent still purely manual work places. As the natural next step, systems capable of pHRI will enter the home sector as home assistants, elderly care assist, and assistive devices ([VIDEO 607](#), [VIDEO 614](#), [VIDEO 618](#), [VIDEO 623](#)) for physically challenged people ([VIDEO 618](#), [VIDEO 619](#), [VIDEO 620](#), [VIDEO 621](#), [VIDEO 622](#)). First, rather basic tasks, such as fetch-and-carry or environment manipulation, will be solved followed by applications with increasing complexity.

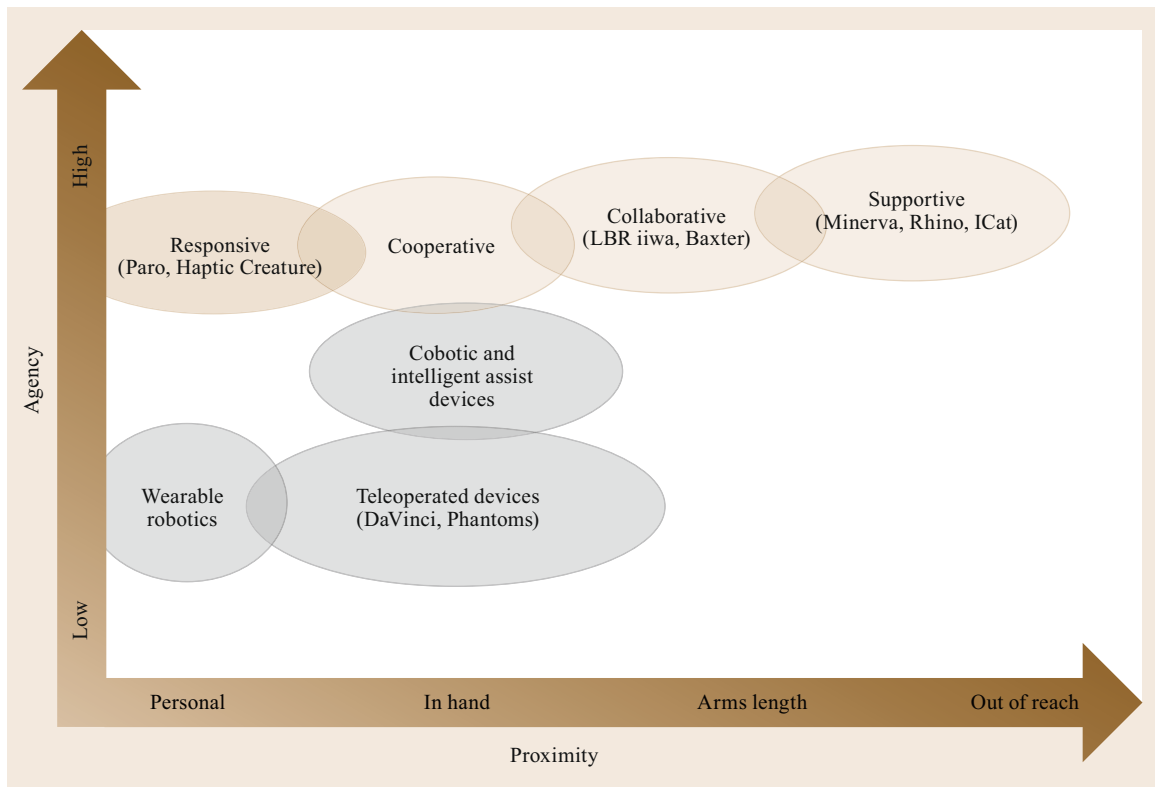

Fig. 69.3 Classification scheme for **pHRI**, by proximity of the interaction and agency (available autonomy) of the robot

69.1.1 Classification of Interaction

pHRI falls into the category of *proximate* interaction where humans and robots are colocated, as opposed to *remote* or teleoperated interaction (Chap. 43) [69.1]. Beyond proximity, the nature of the physical interaction can be understood in the context of the tasks and roles undertaken by the robot and human actors in a **pHRI** scenario. In all of these scenarios, a key feature is the available autonomy, or agency, of the robot partner for performing its portion of the task. This agency separates **pHRI** from Cobotic devices [69.2] and other passive robotic lift assists that require, by design, input from the operator.

Most work in **pHRI** can be generally classified across three broad categories of interaction: *supportive*, *collaborative*, and *cooperative*. Ordered in this way we note that these interactions are marked by increasing frequency and necessity of physical contact with the robot and level of proximity to the user (Fig. 69.3). Further categories include touch-based, personally responsive robots, for example, Paro [69.3] and the Haptic Creature [69.4], and wearable robots (Chap. 70).

In *supportive* interactions, we group interactions where the robot is not integral to the central performance of a task, but instead provides the human with the tools, materials, and information to optimize the human's task performance or objectives, for example, museum tour guide robots, shopping assistant robots for aiding seniors [69.5], and homecare robots (Chaps. 65 and 73). In this context, **pHRI** is typically concerned with safety, that is, preventing and mitigating the effect of unexpected contacts or collisions, and performing appropriate proxemic behavior. When required, physical interaction is infrequent and transitory in nature – typically limited to handoffs or other infrequent transactional exchanges. To support safety, as well as these limited physical interactions, well-structured human–robot communication (Chap. 71) is essential. For example, recent work [69.6–11] has demonstrated the importance of bi-lateral gesture cues in performing turn-taking, information sharing, close proximity activities, and precontact handover operations.

In *collaborative* interactions (👁️ VIDEO 609), the human and robot both work on the task, with the labor divided between the robot and human, each separately completing the parts of the task best suited to their

abilities, but more frequently interacting through turn-taking and part/tool passing [69.12, 13] (👁 VIDEO 716), or haptically enabled mode switching where contact is used to switch the robot's interactive behavior [69.14] (👁 VIDEO 717, 👁 VIDEO 632). In these scenarios, the human completes task elements requiring human dexterity or decision making, while the robot completes elements not well suited to direct human involvement, for example, repetitive or high-force applications, chemical deposition, or precision placement. In both supportive and collaborative interactions, physical space is often shared but planned physical interactions, although much more frequent, are still *transactional* in nature.

Cooperative interactions refer to the extension of cooperative manipulation (see also Chaps. 39 and 70) to include force interactions with humans. This type of interaction is differentiated from Cobots in that the robot operates as an independent agent, rather than a passive assist. That is, the human and the robot work in direct physical contact, or indirect contact through a common object, with continuous and cooperative shared control of the task. Cooperative interactions encompass tasks, such as cooperative lifting and carrying [69.15–17] (👁 VIDEO 613, 👁 VIDEO 820), kinesthetic teaching [69.18] (👁 VIDEO 627), coordinated material handling (e.g., managing long and flexible objects), and rehabilitation therapy (Chap. 64).

69.2 Human Safety

Providing safety in **pHRI** is a multifaceted challenge and requires an analysis on various levels of abstraction. **pHRI** aims at the coexistence of humans and robots in a common workspace and at extending their communication modes by physical means. This spatial proximity leads to a variety of *potential threats*, determined by the current state of the system of interest, which consists of the human(s), the robot(s), and their surrounding environment. Understanding the respective threats, in particular regarding potential human injury originating from physical robot–human contacts, and embedding the insights accordingly into safety standards/regulations is one of the major challenges of

nowadays robotics (note that this chapter does not cover functional safety or robot dependability).

69.2.1 Human Injury in Robotics

Impact Scenarios

In order to quantify human injury that may occur in the context of **pHRI**, one needs to understand how mechanical contacts may cause injury in principle. Figure 69.4 depicts relevant robot–human impact scenarios. These may involve unconstrained impacts, clamping in the robot structure, constrained impacts, partially constrained impacts, and resulting secondary

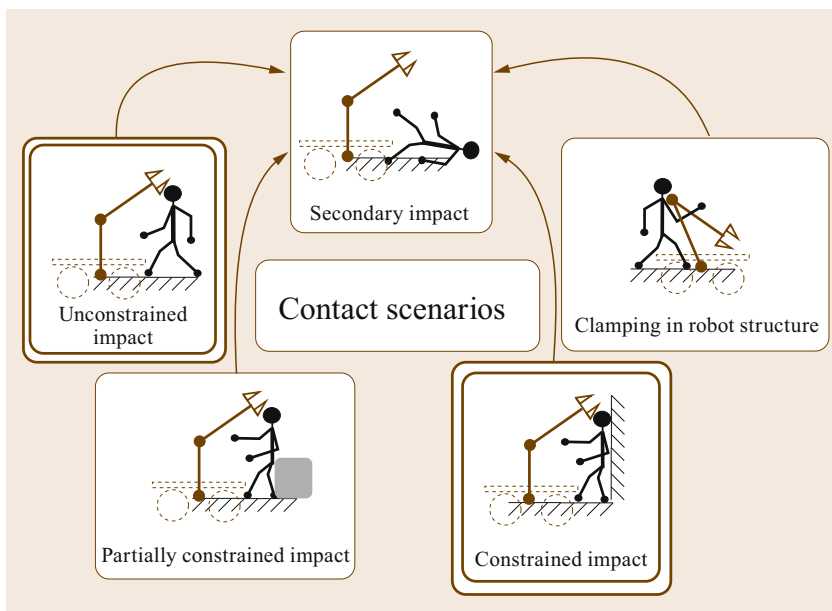

Fig. 69.4 Robot–human impact scenario classes. Unconstrained and constrained impacts are considered the two main scenarios

impacts [69.19]. Apart from such situational definitions, the most urgent question is how to quantify the human injury level that might occur due to a collision between human and robot. The understanding of human injury has been treated in the fields of injury biomechanics and forensics for several decades and the respective studies served for the early work on human injury in robotics. In fact, various injury measures from biomechanics and forensics were applied to human injury analysis in robotics [69.19–25]. An overview on the most important existing injury classification metrics and biomechanical injury measures can be found in [69.26] (VIDEO 608). The most important results from the biomechanics, forensics, and robotics literature are briefly reviewed now.

Overview Biomechanics Literature

In order to derive the injury characteristics of different body parts for direct collisions with an impactor, which is the most relevant case for robotics, countless experiments and publications have been produced over the last

50 years. The investigated impactors used in robotics and biomechanics experiments vary significantly in size and shape. However, from the test setups, one can identify and cluster principal geometric primitives. The main primitives and their parameters are depicted in Fig. 69.5. The z -axis of the coordinate frame associated with each primitive defines the direction of impact u .

Numerous relevant impact experiments with cadavers, volunteers, crash test dummies, and biological tissue for the head, neck, and chest were generated (Tables 69.1–69.4). There for all selected experimental campaigns, the collision scenario, impacted body part, impact parameters according to Fig. 69.5, subject, and impact velocity are listed. For describing the collision scenario, we use the following abbreviations: D: dynamic, QS: quasi-static, U: unconstrained, C: constrained, PC: partially constrained. A collision experiment denoted by **DU** is, thus, dynamic unconstrained, while quasi-static constrained impacts are labeled **QSC** (Sect. 69.2.1, *Synopsis*). The respective impactor type and parameters are listed for comparison.

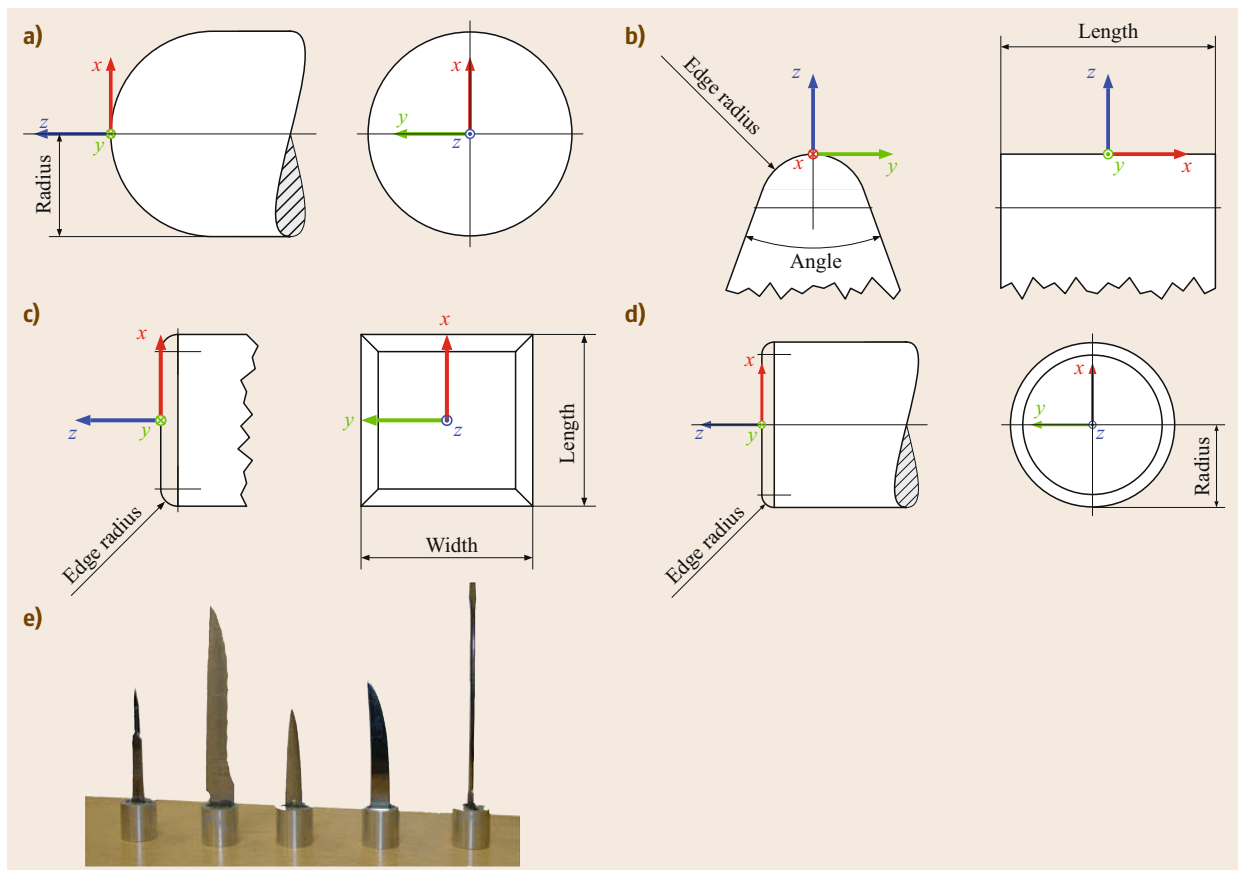

Fig. 69.5a–e Typical impactor primitives with according parameters. (a) Sphere, (b) edge, (c) cuboid, (d) flat circular, (e) sharp tools

Next, some essential characteristics of human–robot impacts are elaborated for a more general understanding of the underlying dynamics.

Robot–Human Impacts

Let us assume that of a serial chain rigid robot consisting of n joints, there is at most a single link involved in a collision. Let

$$\dot{\mathbf{x}}_c = \begin{pmatrix} \mathbf{v}_c \\ \boldsymbol{\omega}_c \end{pmatrix} = \begin{pmatrix} \mathbf{J}_{c,\text{lin}}(\mathbf{q}) \\ \mathbf{J}_{c,\text{ang}}(\mathbf{q}) \end{pmatrix} \dot{\mathbf{q}} = \mathbf{J}_c(\mathbf{q}) \dot{\mathbf{q}} \in \mathbb{R}^6 \quad (69.1)$$

be the stacked (screw) vector of linear velocity at the contact point and the angular velocity of the associated robot link, with an associated (geometric) contact Jacobian $\mathbf{J}_c(\mathbf{q})$ that is a function of the joint angle \mathbf{q} . Accordingly, the Cartesian collision wrench is denoted by

$$\mathcal{F}_{\text{ext}} = \begin{pmatrix} \mathbf{f}_{\text{ext}} \\ \mathbf{m}_{\text{ext}} \end{pmatrix} \in \mathbb{R}^6. \quad (69.2)$$

Robot Collision Modeling. When such a collision occurs, the robot dynamics becomes

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) + \boldsymbol{\tau}_F = \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{ext}}, \quad (69.3)$$

where $\mathbf{M}(\mathbf{q}) \in \mathbb{R}^{n \times n}$ is the symmetric and positive definite joint space inertia matrix, $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} \in \mathbb{R}^n$ is the centripetal and Coriolis vector, and $\mathbf{g}(\mathbf{q}) \in \mathbb{R}^n$ is the gravity vector; $\boldsymbol{\tau} \in \mathbb{R}^n$ is the motor torque, and $\boldsymbol{\tau}_F \in \mathbb{R}^n$ is the dissipative friction torque; $\boldsymbol{\tau}_{\text{ext}} \in \mathbb{R}^n$ is the typically unknown external joint torque given by

$$\boldsymbol{\tau}_{\text{ext}} = \mathbf{J}_c^T(\mathbf{q}) \mathcal{F}_{\text{ext}}. \quad (69.4)$$

The effective mass m_u of a robot acting in the instantaneous collision direction \mathbf{u} , which has to be consistent to $\mathbf{J}_c(\mathbf{q})$, can be deduced from $\mathbf{M}(\mathbf{q})$ via the Cartesian kinetic energy matrix $\boldsymbol{\Lambda}(\mathbf{q})$. This is defined as

$$\boldsymbol{\Lambda}(\mathbf{q}) = [\mathbf{J}_c(\mathbf{q})\mathbf{M}(\mathbf{q})^{-1}\mathbf{J}_c(\mathbf{q})^T]^{-1}, \quad (69.5)$$

where the inverse of $\boldsymbol{\Lambda}(\mathbf{q})$ is based on the decomposition of the kinetic energy matrix

$$\boldsymbol{\Lambda}(\mathbf{q})^{-1} = \begin{bmatrix} \boldsymbol{\Lambda}_v(\mathbf{q})^{-1} & \bar{\boldsymbol{\Lambda}}_{v\omega}(\mathbf{q}) \\ \bar{\boldsymbol{\Lambda}}_{v\omega}(\mathbf{q})^T & \boldsymbol{\Lambda}_\omega(\mathbf{q})^{-1} \end{bmatrix}, \quad (69.6)$$

with $\bar{\boldsymbol{\Lambda}}_{v\omega}(\mathbf{q}) = \mathbf{J}_{c,\text{lin}}(\mathbf{q})\mathbf{M}(\mathbf{q})^{-1}\mathbf{J}_{c,\text{ang}}(\mathbf{q})^T$. Finally, m_u is found to be

$$m_u = [\mathbf{u}^T \boldsymbol{\Lambda}_v(\mathbf{q})^{-1} \mathbf{u}]^{-1}. \quad (69.7)$$

It should be noted that the Jacobian has to be the *center-of-mass-Jacobian*. Otherwise, the entire inverse of the Cartesian inertia tensor has to be used, and not just its translational component block. More details can be found in [69.46]. We assume the local impact curvature in the \mathbf{u} -direction to be denoted by c_u .

Characteristic Robot–Human Impact Force Profile.

A physical collision between robot and human is typically characterized by a distinct force profile that is composed by two consecutive phases (note that for unconstrained soft-tissue collisions these two phases can simplify into a single *Phase I* impact) (Fig. 69.6):

1. Phase I is characterized by a very short impact, governed by the robot- and human-reflected dynamics.
2. Phase II is characterized by a quasistatic contact event. Without clamping, this is a pushing force, whereas if the human is clamped it is a crushing force.

Phase I can be treated from a pure impact physics, almost open-loop point of view, that is, it is determined by the reflected inertia, velocity, and impact curvature c_u of the robot together with the characteristics of the respective body part that is being struck. The maximum contact force is denoted F_I .

Phase II, on the other hand, has to be further subdivided into either *clamping* or *no clamping* incident. In the case of no clamping, the maximum force is F_{IIA} , whereas for clamping, the maximum force is F_{IIB} . In particular, *Phase II* is highly robot control and design dependent and is especially important in the case of clamping:

- *Phase IIA: No clamping.* Typically, for free impacts at robot velocities > 0.3 m/s, F_{IIA} is significantly smaller than F_I . Otherwise, F_I is smaller than F_{IIA} and is governed by the robot actuator torques (active quasistatic pushing) and the reaction of the human body that is mainly governed by its reflected impedance.
- *Phase IIB: Clamping.* In the case of clamping, the final maximum force F_{IIB} is limited by the maximum motor torques $\boldsymbol{\tau}_{\text{max}}$ of the robot via $\mathcal{F}_{\text{ext}} = \mathbf{J}_c^{T\#} \boldsymbol{\tau}_{\text{max}}$, where $\mathbf{J}_c^{T\#}$ is the contact Jacobian pseudoinverse. If the robot is powerful enough to generate active contact forces that penetrate or break human tissue/structure, the contact force is, of course,

Fig. 69.6 Typical robot–human collision force profiles

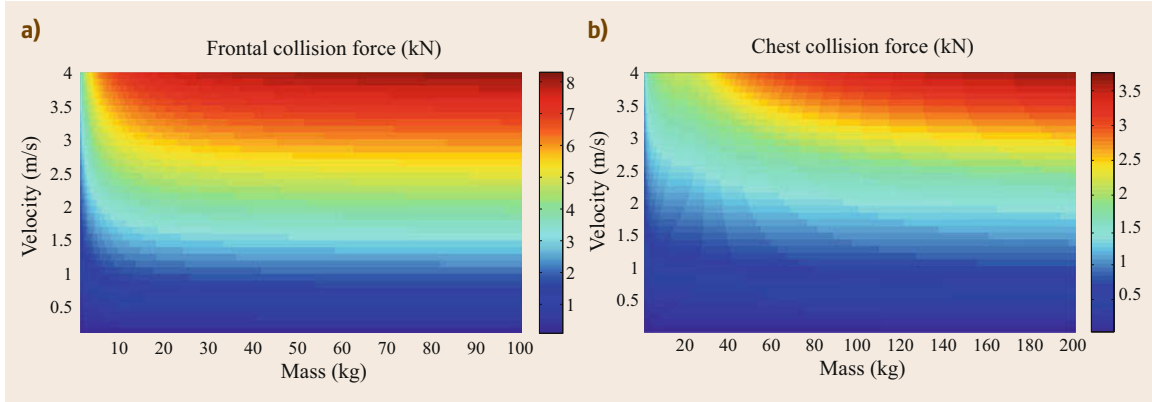

Fig. 69.7a,b Mass–velocity dependency for (a) human head and (b) chest contact force. A mass–spring–mass model is used for collisions against the head, where the head mass M_H is 4.5 kg and the approximate contact stiffness of the frontal bone $K_H = 1000 \text{ N/mm}$ (after [69.33]). For the chest, the model proposed in [69.47] is used

limited by the human maximum tissue resistance. Please note that singularities need careful treatment, which, however, goes beyond the scope of the chapter.

Next, the influence of robot mass and velocity for the unconstrained impact are described. This analysis is particularly important to understand Phase I.

Influence of Robot Mass and Velocity. Assume a simple mass–spring–mass model for the impact between human and robot. M_H is the reflected inertia of the human. K_H is the contact stiffness, which is in the case of a rigid robot mainly the effective stiffness of the human contact area. \dot{x}_{re}^0 is the relative impact velocity between the robot and human. Solving the corresponding differential equation leads to the maximum contact force

$$\mathcal{F}_{ext}^{max} = \sqrt{\frac{m_u M_H}{m_u + M_H}} \sqrt{K_H \dot{x}_{re}^0}. \quad (69.8)$$

Assume a simplifying decoupling of the head from the torso, which holds for the short duration of the impact. For the post-impact phase, neck stiffness and body inertia have to be considered, which complicates the analysis considerably. The dependency of frontal bone contact force on the robot mass and velocity is depicted in Fig. 69.7a. It can be observed that collision force (which is a well-known bone fracture indicator) generally increases with velocity. For increasing mass, however, a saturation effect takes place. After a certain robot mass has been reached ($m_u \approx 20 \text{ kg}$ in Fig. 69.7), additional weight has only negligible influence on collision force. This inertial saturation effect can also be observed for

other impact locations, such as contacts with the chest (Fig. 69.7b).

If the robot mass is significantly larger than the human head mass, that is, $m_u \gg M_H$, (69.8) reduces to

$$\mathcal{F}_{ext}^{max}(m_u \gg M_H) = \sqrt{K_H M_H} \dot{x}_{re}^0. \quad (69.9)$$

This shows that for a robot with significantly larger reflected inertia than the human head, only the contact stiffness, the impact velocity, and the mass of the human head are relevant but not the robot mass.

The behavior of human tissue during collisions is complex. Consequently, surrogates cannot reveal the entire diversity. Accordingly, the conduction of human voluntary experiments is necessary to fully understand human injury and pain dynamics in robotics.

Human–Robot Impact Voluntary Testing

The following experimental test was the first systematic analysis in this direction. The voluntary experiments were conducted with a healthy young adult in the year 2011. The collision experiments were performed with the KUKA/DLR lightweight robot (LWR) and the following approaches to injury and pain analysis were carried out: *injury severity analysis according to AO* (Arbeitsgemeinschaft für Osteosynthesefragen), *biomechanical analysis, pain, and imaging methods*. The setup and experiment steps are depicted in Fig. 69.8. The robotic system allows to conduct controlled robot–human collisions in order to analyze input parameters and their effect on output parameters, such as pain and injury. Measured impact characteristics and quantities included impact force, impact area, tissue displacement, tissue stiffness, stress, impact velocity, kinetic energy, and energy density. The reflected inertia

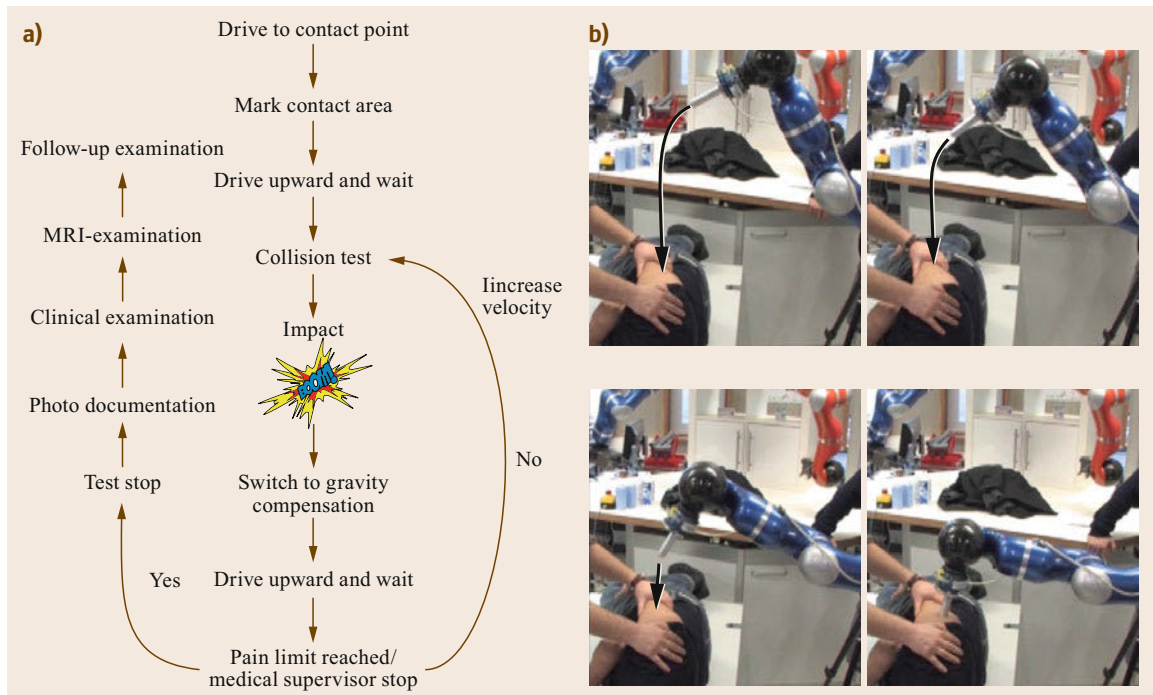

Fig. 69.8 (a) Flow chart depicting the basic experimental steps. (b) Collision trajectory with subject

was kept constant at $m_u = 3.75$ kg for every test. The used impactor for the resulting Table 69.5 was a sphere with a radius of 12.5 mm.

The injury was defined using the AO-classification [69.48] directly after each test series. Each impact series was carried out at the same location on the human body at increasing impact velocity until the participant initiated a controlled system stop during the experiment. The impact areas were then imaged with a magnetic resonance imaging (MRI) after a time interval of about 4–5 h. The remaining tissue did not show any pathological signs. Compared to an equivalent drop test in [69.25] with abdominal pig tissue (large sphere, 4.2 kg, 2.5 m/s), the voluntary experiments provide similar results in terms of injury severity. The maximum velocity of 2.55 m/s is at the border of inducing a contusion. Where there were no marks immediately after impact, a mild contusion formed at day 1. For the pain tolerance at a visual analog scale (VAS) of 6/10, an impact force of $F = 272.2$ N was measured. The energy density appears to have the most significant correlation to pain.

Synopsis

An overview of the potential injury threats depending on the current state of the robot and the human, a classification of these mechanisms, governing factors of the particular process and possible injuries are depicted in

Fig. 69.9. Physical contact can be divided into two fundamental subclasses: quasi-static and dynamic loading. Fundamental differences in injury severity and mechanisms are observed as well if a human is (partially) constrained or not, leading to the second subdivision. For the quasi-static case, it is differentiated between near-singular and nonsingular clamping as already outlined. The last differentiation separates injuries caused by blunt contact from the ones induced by tools or sharp surface elements.

Each class of injury is characterized by possible injuries (PI), worst-case factors (WCFs), and their worst-case range (WCR). WCFs are the main contributors to the worst case, such as maximum joint torque, the distance to singularity or the robot speed. The worst-case range indicates the maximum possible injury depending on the worst-case factors. In addition to the classification of injury mechanisms for each such class, suggestions for injury measures (IMs) are given as well. They are specific injury measures which are appropriate, useful for the classification and measurement of injury potentially occurring during the physical human–robot interaction. Please note that the list of injury measures is not necessarily complete, but these ones are certainly suitable to be applied to a more granular robotics injury analysis. This does not mean that criteria, such as the well-known head injury criterion (HIC), do not provide general insights; they are just not

necessarily optimal to understand injury on a more differentiated lower-injury scale.

For example ① in Fig. 69.9 represents blunt clamping in the near-singular configuration (Fig. 69.9). Even for low-inertia robots, this situation could become dangerous and is, therefore, a possible serious threat with almost any robot on a fixed base within a (partially) confined workspace. Possible injuries are fractures and secondary injuries, for example, caused by penetrating bone structures or an injured neck if the trunk is clamped but the head is free. This would mean that the robot pushes the head further, while the trunk remains in its position. Another possible threat is shearing off a locally clamped human along an edge. Appropriate indices are, for example, the contact force and the compression criterion (CC) [69.49]. ③ in Fig. 69.9 represents the clamped blunt impact in nonsingular configuration. The injury potential is defined by the maximum actuation torque τ_{\max} and can range from no injury to severe injury or even death for high-inertia (and torque) robots. The robot stiffness does not contribute to the worst case since a robot without collision detection would simply increase the motor torque to follow the desired trajectory. Therefore, robot stiffness only contributes to the detection mechanism by enlarging the detection time. Also, the contact force and CC are well suited to predict occurring injury. ⑧ in Fig. 69.9 denotes the unconstrained impact which was the first injury mechanism investigated in the robotics literature. This process is governed by the impact velocity and (up to a saturation value) by the robot mass. As shown in [69.22], even a robot of arbitrary mass cannot severely injure a human head by means of impact-related criteria from the automobile industry like the head injury criterion (HIC). However, fractures, for example, of facial bones are likely to occur but not all would be classified as a serious injury. Laceration by

means of crushes and gashes are worth evaluating, especially with respect to service robotics. The contact force and CC are well-suited severity criteria for this class. In order to evaluate lacerations the energy density has to be considered.

The preceding overview is intended as a worst-case analysis for the described contact cases. The next step is to ask which actions can be taken against each particular threat [69.19]. At this point, however, it shall be noted that instead of quantifying injury in terms of a measurable injury criterion, injury evaluation by a medical expert, for example, via the AO-classification can always be applied and would presumably result in a more exhaustive and precise judgement.

69.2.2 Safety Standards for Human–Robot Interaction

Robotics standardization made significant progress to establish the underlying regulations for co-working cells in the real world. Safety for industrial robots is addressed in a variety of general standards [69.50–52]. The most important industrial robotics standards is the International Organization for Standardization (ISO) 10218. It was established in the recognition of the particular hazards that industrial robots and industrial robot systems may pose. The machinery concerned and the extent to which hazards, hazardous situations, and events are covered are indicated in the scope of ISO 10218. In recognition of the variable nature of hazards with different uses of industrial robots, ISO 10218 is divided into two parts. It provides a detailed analysis of mechanical hazards, such as impacts, crushing, shearing, entanglement, drawing-in or tapping, cutting or severing, and contact of persons with live parts (direct contact) [69.53]. In particular, the introduction of collaborative robots has been a ma-

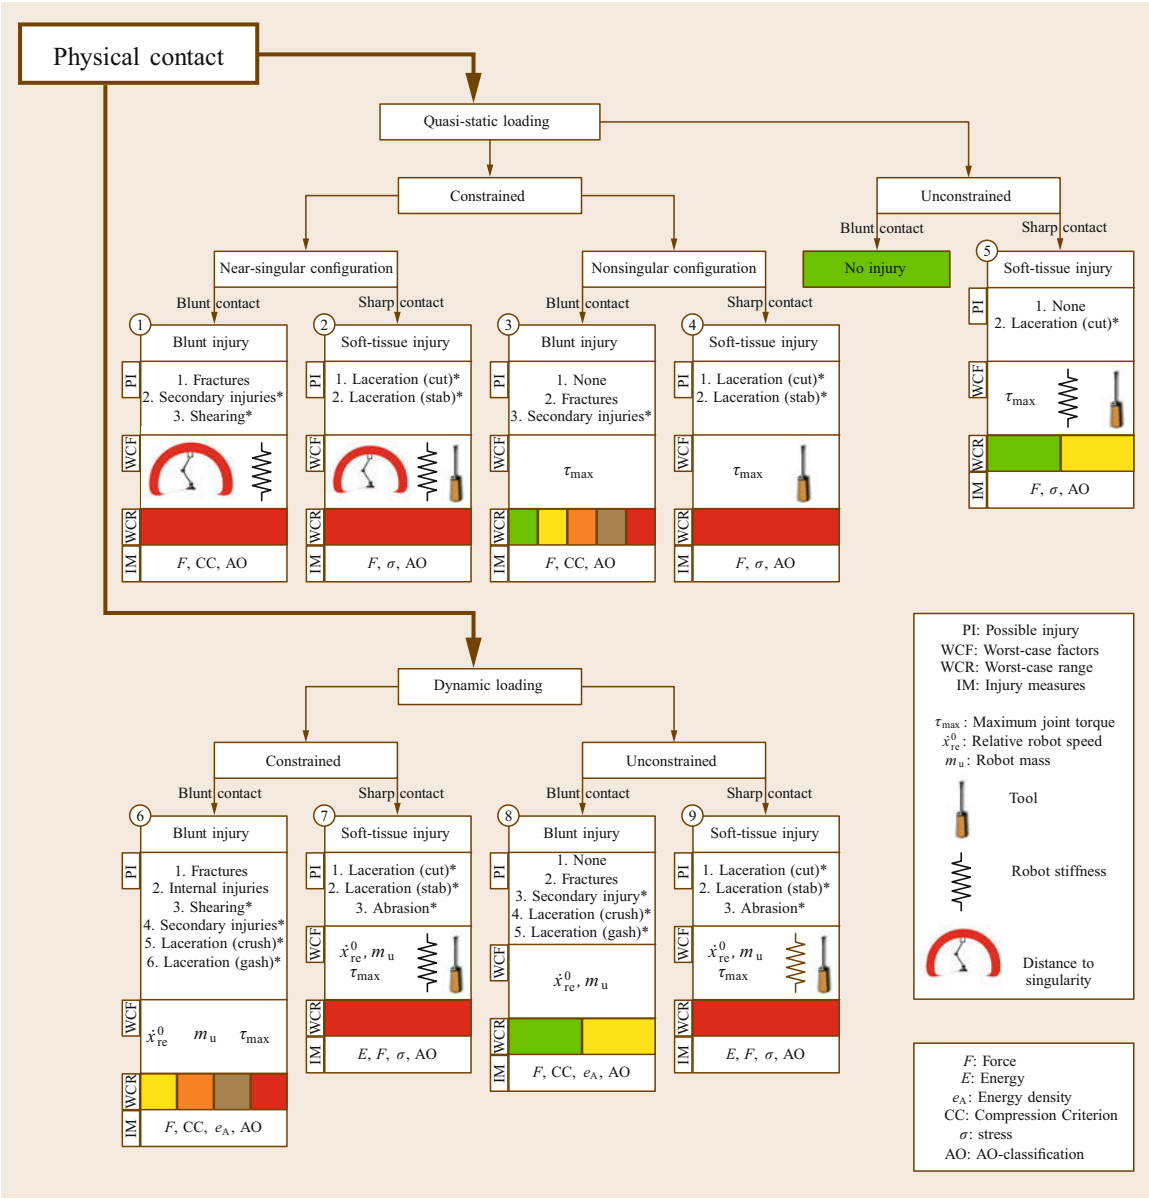

Fig. 69.9 Safety tree showing possible injury (PI), major worst-case factors (WCF) and the possible worst-case range (WCR). * indicates still ongoing topics of research. Additionally, relevant injury criteria are given for the head, chest, and soft-tissue injuries

for acknowledgment to the advances made in robotics research in pHRI over the last decade. The recent updates to ISO 10218 (safety requirements for industrial robots) led to the development of the new technical specification (TS) 15066. It is regarded as a complementary information that concretizes the content of ISO 10218. Generally, ISO/TS 15066 provides guidance for collaborative robot operation where a robot and a person share the same workspace. It considers collab-

orative modes and requirements, such as minimum separation distances, safety-rated monitored stops, speed and separation monitoring, and power and force limiting. In collaborative operations, the integrity of the safety-related control system is of major importance, particularly when process parameters, such as speed and force, are being controlled. A comprehensive risk assessment is required to assess not only the robot system itself, but also the environment in which it is

placed, that is, in the workplace. A key process in the elimination of hazards and reduction of risks is the design of the collaborative robot system and the associated cell layout. Various considerations about the access and clearance of the collaborative workspace are provided. During the design of a robotic system, the maximum space and the restrictions of the collaborative robot system have to be considered. Furthermore, the need for clearances around obstacles and the accessibility for operators should influence the design. The intended contact(s) between parts of the robot system and an operator plays a major role toward a possibly intrinsically safe design. In order to identify the risks resulting from the collaborative action, an appropriate set of collision incidents that can occur during the collaborative work activities and foreseeable misuse has to be determined. This has to include affected body regions and the involved collision areas of the robot. The limit values that may not be exceeded during the collision incident depend on the affected body regions. The geometry of the involved areas of the robot and the biomechanical properties of the affected body regions influence the forces occurring during the collision incident. Therefore, the [ISO/TS 15066](#) describes injury severity criteria that consist of maxi-

mum allowable limit values on individual body regions. These limit values are established to prevent the occurrence of skin/tissue penetrations that are accompanied by bleeding wounds, fractures, or other skeletal damage [69.54].

In addition to the industrial standardization efforts in the [pHRI](#) domain, the [ISO 13482](#) [69.55] is the first nonindustrial robot safety standard that allows/regulates close [pHRI](#). This international standard specifies requirements and guidelines for the inherent safe design, protective measures, and information for the use of so called *personal care robots*. It focuses on three types of personal care robots (mobile servant robots, physical assistant robots, and person carrier robots). These robots typically perform tasks to improve the quality of life of intended users irrespective of age or capability. The standard describes hazards associated with the use of these robots and provides requirements to eliminate or reduce the risks associated with these hazards to an acceptable level. Significant hazards are presented and this standard describes how they are to be dealt with for each personal care robot type. Robotic devices used in personal care applications are also covered by this standard and are to be treated as personal care robot.

69.3 Human–Friendly Robot Design

Designing robots for interaction has become a challenging subdomain in [pHRI](#), leading to novel devices that have one thing in common: active and/or passive compliance together with lightweight design being the central design paradigms. A number of research-focused robots have been designed specifically for [pHRI](#). The most important design guidelines, representatives, and modeling basics are outlined in this section. Apart from robots that are designed to act as general purpose co-workers, large robot assists with balanced, inertia reducing, cable-driven gantry systems can be used to create large payload robots that may be operated next to human workers [69.56].

69.3.1 Lightweight Design

In the process of making robots inherently suitable for close physical interaction with humans or only partially known environments, a design paradigm shift moving away from heavy, stiff, and rigid designs toward lightweight and highly integrated mechatronics designs has taken place. Low inertia and high (active) compliance have become desirable features, as has the use of

redundant sensing principles on the proprioceptive level (position, velocity, and torque).

General Characteristics

Generally, two major design approaches for lightweight robots have proven successful over the last years [69.57], namely the *mechatronics approach* and the *tendon-based approach*, respectively. Their commonalities are as listed:

- *Lightweight structures*: Lightweight, high-strength metals, or composite materials for the robot links. Moreover, the design of the entire system (controllers, power supply) is optimized for weight reduction to enable mobility.
- *Low power consumption*: This is mainly achieved by small moving inertias and accordingly designed motors.

Typically, *mechatronic robots* integrate electronics into the joint structure for allowing highly modular units. Such a design enables the assembly of different kinematics with increasing complexity, while keeping the respective joint philosophy. In terms of actuation,

Fig. 69.10 (a) Barrett arm (after [69.58]), (b) Mitsubishi PA10 arm, (c) DLR lightweight robot III (after [69.59]), (d) KUKA LBR iiwa (after [69.60]) (courtesy of Barret Technology Inc., DLR, KUKA)

the combination of high power/torque motors with high transmission ratio gears is usually applied. From the proprioceptive sensing side, these systems are typically equipped with additional sensors, such as joint torque, force, and current sensing in addition to basic motor side position and current sensing only (Sect. 69.3.3).

Tendon-based robots have three major characteristics. First, they are typically equipped with remote direct drives. This reduces the overall weight of moving parts for a fixed base manipulator as the actuators are located in the robot base. For placing the actuators remotely from the base, cable-pulley systems are usually applied. Finally, low reduction ratios are used for keeping the system backdrivable. In turn, larger motors have to be selected, which adds additional total weight.

Another interesting class of compliant actuators is of note that implements compliance quite differently. They use rheological fluids such that they can alter their characteristic properties under the influence of either a magnetic or an electric field. A clutch between link and motor is operated in such a way that the output torque can be controlled. These actuators were also mo-

tivated and discussed from a human-safety perspective in [69.61].

Lightweight Robotic Systems

The most prominent robots that fall into the category of lightweight robots are depicted in Figure 69.10. The *Barrett arm* is a classic example of a *tendon-based design*, where the actuators are placed in the manipulator base and the joints are backdrivable due to the low reduction ratio. The *Mitsubishi PA10* arm was a commercially available lightweight redundant arm, with a weight of 38 kg and a payload of 10 kg. The fully torque-controlled *KUKA LBR iiwa* is based on the DLR lightweight robot technology [69.60]. Its third generation DLR LWR-III weighs 13.5 kg and is able to handle loads up to 15 kg, so an approximate unitary payload-to-weight ratio is achieved. The robot is equipped with joint torque sensors in each joint and has redundant position measurement (on motor and link side) [69.62].

Apart from single-arm robots as described above, various lightweight designs were also successfully integrated into research and commercial humanoid systems

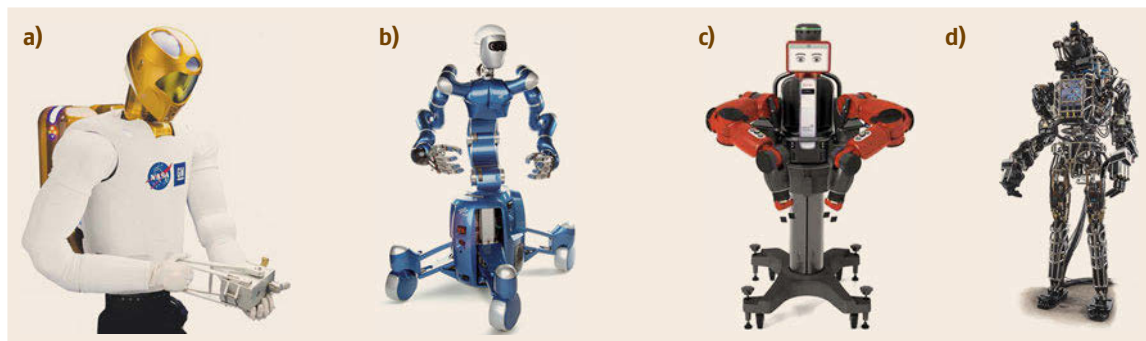

Fig. 69.11 (a) NASA Robonaut 2, (b) DLR Rollin' Justin, (c) Rethink Robotics Baxter and (d) Boston Dynamics Atlas (courtesy of NASA, DLR, Rethink Robotics Inc., Boston Dynamics)

(Fig. 69.11). The NASA (National Aeronautics and Space Administration) *Robonaut 2* [69.63], equipped with SEA, was originally designed for teleoperation and exploration in space [69.64]. The fully torque-controlled humanoid robot *TORO* [69.65], based on the DLR lightweight robot technology, has its origins in the upper body bimanual system *Justin* [69.66] (VIDEO 626). Rethink Robotics *Baxter* is a commercial two-arm upper body system for pick and place tasks that is equipped with SEA for torque measurement purposes. The hydraulically actuated humanoid, *Atlas* from Boston Dynamics, is one of the systems that entered the DARPA (Defense Advanced Research Projects Agency) *Robotics Challenge*.

Modeling Lightweight Robots

For a robot with n viscoelastic joints, the so-called reduced model of *Spong* [69.67] has become the standard way of modeling lightweight robots. When including also the presence of joint torques due to contact forces (on the link dynamics), we shall consider the following dynamic model of robots with viscoelastic joints:

$$\mathbf{M}(q)\ddot{q} + \mathbf{C}(q, \dot{q})\dot{q} + \mathbf{g}(q) = \boldsymbol{\tau}_J + \boldsymbol{\tau}_{\text{ext}}, \quad (69.10)$$

$$\mathbf{B}\ddot{\boldsymbol{\theta}} + \boldsymbol{\tau}_J = \boldsymbol{\tau}. \quad (69.11)$$

The generalized coordinates are doubled since there will be a dynamic displacement $\boldsymbol{\delta} = \boldsymbol{\theta} - \mathbf{q}$ between the motor positions $\boldsymbol{\theta} \in \mathbb{R}^n$, as reflected through the gear ratios, and the link positions \mathbf{q} . The matrix $\mathbf{B} = \text{diag}(B_i) \in \mathbb{R}^{n \times n}$ is the diagonal, positive definite motor inertia matrix. We define the *elastic joint torque* transmitted through the joints and coupling (69.10) and (69.11)

$$\boldsymbol{\tau}_J = \mathbf{K}_J(\boldsymbol{\theta} - \mathbf{q}) + \mathbf{D}_J(\dot{\boldsymbol{\theta}} - \dot{\mathbf{q}}), \quad (69.12)$$

where $\mathbf{K}_J = \text{diag}(K_{J,i}) \in \mathbb{R}^{n \times n}$ is the diagonal, positive definite joint stiffness matrix, and $\mathbf{D}_J = \text{diag}(D_{J,i}) \in \mathbb{R}^{n \times n}$ is the diagonal, positive semidefinite joint damping matrix. The quantity $\boldsymbol{\tau}_J$ in (69.12) is also the output of joint torque-sensing devices, when available. In many practical cases, the mechanical design of the transmission/reduction elements is such that one can neglect the joint damping, that is, $\mathbf{D}_J \simeq \mathbf{0}$. Joint elasticity has long been addressed for lightweight robot systems, however, more as an undesired consequence that the control has to handle [69.68]. This requires advanced control techniques in order to obtain accurate, performant motion. For a complete overview on the properties of robots with joint elasticity effects, please refer to Chap. 11.

69.3.2 Intrinsically Flexible Design

Recently, the class of intrinsically flexible actuators and robots have become increasingly popular. Inspired by the flexible properties in biological muscles, compliant joints are designed with the aim of imitating human or animal motions during various tasks. The main idea of intrinsically flexible actuation is to come closer to human capabilities in terms of speed and shock absorption. This is not realizable with today's rigid industrial robots, when assuming approximately the same torque range or weight as humans have. By storing and releasing energy in the joints, one aims for improvement in tasks, such as running or throwing [69.69–72] where humans still clearly outperform robots. In Chap. 21 and [69.73], a more in depth review of intrinsically flexible actuation is presented. In this chapter, we review only the relevant insights for placing the technology in the pHRI context.

General Characteristics

Roughly speaking, intrinsically flexible actuators can be divided into two categories:

- Actuators with fixed mechanical impedance, where the effective joint impedance is altered via active control. The most well-known example is the series elastic actuator (SEA) [69.74], whose acronym became a generic term for this class of actuators.
- Actuators where the impedance can be adjusted by altering mechanical joint properties, such as stiffness and damping. There exist various categories like variable stiffness actuators (VSAs) that allow stiffness changes or variable impedance ac-

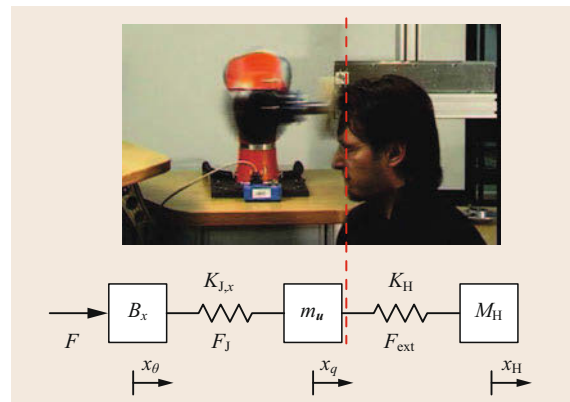

Fig. 69.12 Human–robot collision in operational space, which is defined by the reflected flexible dynamics of the robot and the local contact stiffness/mass properties of the human head

tuators (VIAs) that enable more general impedance changes, including damping adjustment.

The original motivation for introducing VSA and VIA, for example, in [69.20], was to make robots safer during unforeseen collisions due to dynamic decoupling of the motor and link-side inertia from each other. This effect reduces the collision danger by alleviating the impacting robot inertia. In [69.20], it is, for example, shown that HIC could be reduced by introducing elasticity in the joint. This idea was generalized and systematically analyzed in [69.75, 76], and is summarized here.

In order to simplify the human robot collision analysis basic models in operational space coordinates were used for this analysis (Fig. 69.12). For this, operational space coordinates and reflected inertias/stiffnesses along an arbitrary instantaneous impact direction \mathbf{u} are considered [69.46]. The masses $M_H, m_u, B_x \in \mathbb{R}^+$ are the reflected human, link, and motor mass. $K_H, K_{J,x} \in \mathbb{R}^+$ are the reflected (human) contact stiffness and joint/structural elasticity. The projected human, motor, and link impact position are denoted by x_H, x_θ , and $x_q \in \mathbb{R}$, respectively. $x_\theta = p_u(T(\theta))$ and $x_q = p_u(T(q))$ are defined via the respective forward kinematics maps projected in the \mathbf{u} -direction.

As pointed out in [69.20], a robot with quite low reflected link inertia $m_u = 0.1$ kg is able to reduce the impact forces significantly if a contact stiffness of $K_H = 5$ kN/m is assumed. Similar to the work in [69.21], it was shown that a decrease in joint stiffness can significantly reduce the impact characteristics and, thus, is a powerful countermeasure against large contact forces. In [69.77], it was deduced that for the case of a 2-DOF (degree of freedom) planar intrinsically compliant robot, already slightly touching a rigid wall with its second link, the compliant mechanism can limit the maximum static force/torque effectively if the motor torque is slowly increased. It is, of course, unquestionable that joint elasticity decouples the motor from the link. However, as was indicated in [69.22], a reduction in joint stiffness cannot reduce the impact characteristics during very rigid, fast, and blunt crash-test dummy impacts for a lightweight system, such as the LWR-III (which is basically an SEAs type robot from a modeling perspective). This was proven by measuring the decoupling of motor and link inertia via the integrated joint torque sensors and the additionally recorded external contact force.

Figure 69.13 depicts the experimental evidence for a collision at 1 m/s between a DLR LWR-III and a stationary unconstrained Hybrid III dummy (HIII) head on the frontal area [69.22]. The contact force f_{ext} was measured with a high-speed force sensor $f_{\text{ext,fs}}$ and for consistency check with a triaxial accelerometer $f_{\text{ext,as}}$.

As one can see, the simulation and experimental signals show very good consistency. Clearly, the projected elastic joint force f_j reacts delayed to the collision, thus proving the desired decoupling property already for such an intrinsically very stiff robot. For the impact simulation, a reflected stiffness of 6.72×10^4 N/m is chosen, which represents a realistic joint stiffness and structural elasticity value. The reflected motor inertia is $B_x = 13$ kg and the reflected link side inertia $m_u = 2$ kg. The dummy head mass is $M_H = 4.5$ kg and the contact stiffness is $K_H = 3.2 \times 10^5$ N/m.

This result showed that already the compliances of the built in gear and the joint torque sensor is sufficient to decouple the motor from the link, making it entirely unnecessary to further reduce joint stiffness for the given robot for this purpose. There are two main aspects, which have to be considered to fully understand this result. On the one hand, the contact stiffness of the crash-test dummy used is significantly larger than the reflected elasticity of the DLR LWR-III; however, it is also realistic for the human frontal area [69.27]. Furthermore, the reflected motor and link inertia for the DLR LWR-III are the same order of magnitude as for the human head mass. This is quite reasonable for a full-scale lightweight robot arm.

Two further benefits of inherent compliance are as follows. First, the robot itself is able to resemble compliant behavior without the inherent need for high-performance force/torque feedback. Please note that it is not possible to display arbitrary Cartesian stiffness behavior for a robot with diagonal stiffness matrix only [69.79]. Second, the joint elasticity acts in combination with the link inertia as a mechanical low-

Fig. 69.13 Impact experiment and simulation of a LWR-III with a Hybrid III Dummy. The experimental contact force is measured for consistency check with a high-speed acceleration (as) and force sensor (fs) simultaneously

Fig. 69.14a–c Passively flexible anthropomorphic robots: compliant humanoid platform (COMAN, (a)) from IIT (after [69.78]), Valkyrie (b) from NASA, and hand arm system (HASY, (c)) from DLR (courtesy of IIT, DARPA, DLR)

pass filter, thus protecting the drive train from impact shocks; that is, it makes the system inherently more robust [69.71, 80].

Another interesting use of elasticities in the drive train of a manipulator relates to the fact that it can serve as a storage mechanism for potential energy, and be used to increase a robot's link speed beyond the maximum motor velocity [69.70, 71, 80–82]. This ability strongly influences the safety of intrinsically elastic systems, as a robot's impact speed determines its inherent collision danger to a large extent. However, we refer to [69.75] for further details on this matter, where the effect of a robot's elastic speed increase on potential danger in terms of HIC is derived.

Intrinsically Flexible Robotic Systems

Figure 69.14 shows some of the most prominent recent anthropomorphic/humanoid devices that employ passively compliant actuators. The COMAN system of IIT (VIDEO 624) is a full-scale SEA robot, as is NASA's Valkyrie. Both system's ability to measure torques results from the ability to flex around their joint axes and then relate this elastic deflection to the joint torque. The DLR hand-arm system [69.72] is fully equipped with VSA in every joint, while having approximately human size, strength, and dexterity.

Modeling Passively Flexible Robots

From a formal modeling point of view, lightweight robots and robots with fixed mechanical impedance are

very similar. The main difference lies in the respective torque sensor measurement principle. The joint elasticity in lightweight robots is rather high and allows only for small deflections between the motor and link position. The stiffness in compliant actuators, however, is intentional and typically at least an order of magnitude lower, thus enabling significantly larger deflections. Consider the elastic joint model (69.10) and (69.11) from Sect. 69.3.1, which under certain mild conditions also holds for intrinsically elastic robots. The main difference is that for lightweight robots, $K_{J,i}$ is large compared to SEA-like systems. For many VSA systems, the transmitted torque can be expressed as

$$\tau_J = f(\delta, \sigma), \quad (69.13)$$

where σ denotes a stiffness adjustment control input (typically the position of a second motor). The torque–displacement curve $f(\delta, \sigma)$ may exhibit different characteristics, such as being strictly increasing $\partial f(\delta, \sigma)/\partial \delta > 0$ and convex $\partial^2 f(\delta, \sigma)/\partial \delta^2 > 0$. More details on implementations can be found in [69.73].

69.3.3 Perception for Interaction

The recent advances in pHRI benefit greatly from previous achievements in contact and noncontact sensors and sensing techniques. In the current chapter, we shortly review the essential sensing techniques that had strong

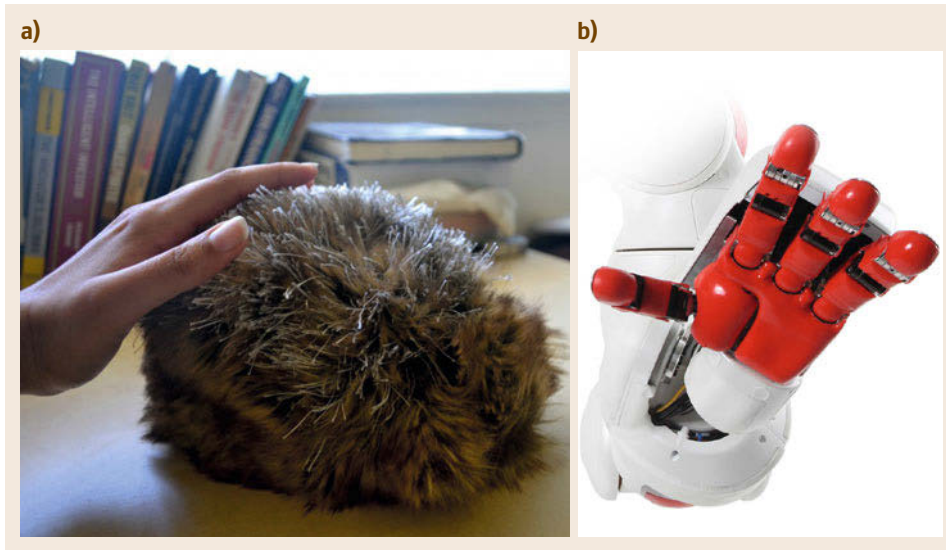

Fig. 69.15 (a) Furry robot *skin* utilizing piezo-resistive fabric and conductive sensors provides a low cost design concept with high tactile gesture recognitions rates (after [69.83]). (b) The hand of TWENDY-ONE with integrated distributed pressure sensors (courtesy of Karon MacLean, UBC, Shigeki Sugano Lab., Waseda University)

impact on pHRI and focus on the underlying main concepts. Chapters 28 and 32 give a full view and can be consulted for further details.

69.3.4 Proprioceptive Force/Torque Sensing

Many robot arms have the option to include a six-axis force/torque sensor at the wrist, enabling not only force control-based manipulation, but also symbolic haptic interaction [69.84, 85], possibly also based on joint torque sensing. More recently, torque sensors have been integrated into the joints of commercial robots, for example, into the KUKA LWR [69.86]. This allows for contact sensing along the entire robot structure with measurements of contact magnitude, direction, and knowledge of which link was contacted [69.87].

Essentially, two major sensing principles for joint torque measurement exist: either by directly measuring the torque which is typically done via strain gauges, or by measuring it implicitly via the deflections δ between link and motor position. For this, it is assumed that δ directly relates to torque typically by a constant multiplier, the joint stiffness $K_{J,i}$. For the latter, both link- and motor-side position sensors need to be mounted. The first works that aimed at developing and minimizing torque-sensing devices can be found in [69.88–90]. The torque-sensing principle has also a strong relation to the design classification in Sect. 69.3.

69.3.5 Tactile Perception

Several tactile skins have been developed over the years such as, for example, [69.91–94]. In the latter work, for example, the human skin served as a design metaphor. Therein, a solution of the goal conflict between the desired high sensitivity and the required mechanical robustness is in the focus. Furthermore, beyond providing the required sensory capability, the mechanical deformation and damping properties necessary for the operation of the robotic system are considered as well. Using whole-arm tactile sensing across the manipulator surface explicitly allows the sensing of multiple contacts; for example, in [69.95], the authors operate a robot in a cluttered environment in order to successfully reach a goal that is occluded by obstacles using a model predictive controller. Other recent examples of localized sensors include touch pads placed at key points on the robot [69.96], and force-sensitive resistors distributed over the robot [69.97]. The latter example is used in a novel haptic robot designed to both read and display emotion mediated through cues sensed primarily through physical interaction. These methods have the advantage of using reliable and fairly precise sensors, but are capable of measuring contact only at discrete locations. For more extensive contact sensing, several researchers have developed various types of robot skin; that is a distributed sensor network that covers extensive areas and measures diverse qualities of contact events, including location, magnitude, orientation, and temperature. Hard robot skins or shells have been used to

Fig. 69.16 Low cost 3-D-RGB-D cameras: (a) Microsoft Kinect (Wikipedia Commons), (b) Asus Xtion (courtesy Asus)

detect collisions [69.98], while soft robot skins that can conform to different robot shapes have been used for more complex, often social or affective, human–robot interaction, for example, [69.99]. While robot skin can add significant sensing capability to robots, it may also add to the complexity and cost, and thus compromises the robustness of the robot. However, recently a furry *creature* skin (Fig. 69.15) was created [69.83] using a combination of low-resolution piezo-resistive fabric, and conductive fur sensors to create a low-cost robot covering with 90% interaction gesture (stroking, patting, poking, hitting) recognition rates when trained on an individual and 68–80% recognition rates when trained on groups (👁️ VIDEO 615). A detailed review of tactile sensing technology for human–robot interaction can be found in [69.100]. Other examples can be found in Chap 28.

69.3.6 Visual Perception

Visual (noncontact) sensing is very important for preparing for pHRI. Tracking and planning for the location of a human partner and predicting, for example, the motion of the partner’s hand is an important precursor to a successful handover operations [69.12]. While well-known marker-based systems, such as Vicon and Optotrak systems, provide very high resolution tracking systems, they are impractical for day-to-day use. The development of low-cost 3-D-RGB-D (three-dimensional red green blue depth) cameras (Fig. 69.16) permits the 3-D tracking of full body models in large and partially occluded spaces, with ongoing improvements toward robustness in body pose tracking and for tracking of hand gestures [69.101, 102].

69.4 Control for Physical Interaction

For soft and safe pHRI, the question arises how to gently handle physical contact in robotics from a control point of view. As impedance control [69.103] became the most popular interaction control paradigm in the pHRI world, this particular scheme will be one focus of this section. Its generalization to multipriority impedance control laws allows the realization of sophisticated robot compliance with multiple objectives via active control. A major advantage of impedance control is that discontinuities like contact–noncontact do not create stability problems as they occur, for example, with hybrid force control [69.104]. Its extension to impedance and feed-forward learning and adaptation, for which the first works can be found in [69.105, 106], is discussed after introducing the concept of multipriority impedance control. Apart from nominal interaction control, a robot sharing its workspace with humans and physically interacting with its environment should be able to quickly detect collisions and safely react to them. In the absence of external sensing, relative

motions between robot and environment/human are unpredictable and unexpected collisions may occur at any location along the robot arm. The state-of-the-art schemes for collision detection and reflex reaction are introduced. Finally, the last part of the section deals with the shared manipulation problem, one of the standard application examples of pHRI.

69.4.1 Interaction Control

Originally developed for robust and compliant object manipulation, impedance and the related admittance control (👁️ VIDEO 610) form a paradigm to treat robotic systems from an energetic point of view such that motion and force can be controlled in a unified manner. They offer the advantage over hybrid force-motion controllers to provide a framework independent from kinematic work space constraints. These control types popularized by [69.103] are also especially advantageous in terms of uncertainties and disturbances in

unknown environments due to their inherently robust nature [69.107]. The terms impedance and admittance, are derived from electrical system theory where they describe the relationship between voltage and current as input/output pairs. To generalize impedance and admittance such pairs can be defined domain-independently as effort and flow variables. For robotics, the mechanical analogies, that is, mechanical impedance and admittance are of particular interest.

More details on the conceptual basics of impedance and the dual admittance control can, for example, be found in [69.108, 109]. Furthermore, Chap. 9 gives a more thorough basis on force control strategies in general and impedance control in particular.

The mostly used version of impedance control is to impose a second-order dynamics of a mass–spring–damper system (so-called target impedance [69.103]) on the closed-loop equations. Typically, the control objective is expressed in operational space coordinates \mathbf{x} as

$$\mathbf{M}_x \ddot{\tilde{\mathbf{x}}} + \mathbf{D}_x \dot{\tilde{\mathbf{x}}} + \mathbf{K}_x \tilde{\mathbf{x}} = \mathcal{F}_{\text{ext}}, \quad (69.14)$$

where $\tilde{\mathbf{x}} := \mathbf{x} - \mathbf{x}_d$ is the position error and \mathbf{x}_d is called equilibrium position. \mathbf{M}_x denotes the desired inertia, while \mathbf{D}_x and \mathbf{K}_x are the according closed-loop damping and stiffness matrices in operational space. \mathcal{F}_{ext} denotes the external wrench acting at the end-effector of the robot. Assuming rigid body dynamics, the control law to obtain the aforementioned behavior is

$$\begin{aligned} \boldsymbol{\tau}_{C^*} = & \mathbf{g}(\mathbf{q}) + \mathbf{J}(\mathbf{q})^T [\boldsymbol{\Lambda}(\mathbf{q}) \ddot{\mathbf{x}}_d + \boldsymbol{\mu}(\dot{\mathbf{x}}, \mathbf{x})] \\ & - \mathbf{J}(\mathbf{q})^T [\boldsymbol{\Lambda}(\mathbf{q}) \mathbf{M}_x^{-1} (\mathbf{K}_x \tilde{\mathbf{x}} + \mathbf{D}_x \dot{\tilde{\mathbf{x}}})] \\ & + \mathbf{J}(\mathbf{q})^T [\boldsymbol{\Lambda}(\mathbf{q}) \mathbf{M}_x^{-1} - \mathbf{I}] \mathcal{F}_{\text{ext}}. \end{aligned} \quad (69.15)$$

In order to fully implement this scheme, a wrist force torque sensor is necessary for the inertia shaping part. In [69.110], a modified impedance controller was designed that uses angle/axis representations for the rotational components of the operational space. For its derivation, energy contributions with physical interpretation are considered and the end-effector orientation displacement representation is chosen to be in terms of a unit quaternion to avoid singularities.

For redundant robots, it is typically desired to also control the nullspace behavior in order to embed other control objectives $\boldsymbol{\tau}_{N,i}$ into a stacked hierarchy of tasks (Chaps. 17 and 36). For the case of a single nullspace controller $\boldsymbol{\tau}_N$, this torque has to be projected via the nullspace projector matrix $\mathbf{N}(\mathbf{q})$ into the nullspace of the task, leading to the overall control law

$$\boldsymbol{\tau}_C = \boldsymbol{\tau}_{C^*} + \mathbf{N}(\mathbf{q})^T \boldsymbol{\tau}_N. \quad (69.16)$$

The nullspace projection matrix can be chosen in different ways. The simplest case is $\mathbf{N}(\mathbf{q}) = \mathbf{I} - \mathbf{J}(\mathbf{q})^\# \mathbf{J}(\mathbf{q})$,

where $\mathbf{J}(\mathbf{q})^\#$ denotes the Moore–Penrose pseudoinverse. Alternatively, one may choose the *dynamically consistent* generalized pseudoinverse

$$\mathbf{J}(\mathbf{q})^\# = \mathbf{M}(\mathbf{q})^{-1} \mathbf{J}(\mathbf{q})^T \boldsymbol{\Lambda}(\mathbf{q}). \quad (69.17)$$

In particular, in the pHRI domain, a multitude of different subtasks $\boldsymbol{\tau}_{N,i}$ are meaningful to be executed simultaneously. These may, for example, involve:

- Safety (collision anticipation and avoidance, self-collision avoidance, ...)
- Physical constraints (joint limits, geometric task constraints)
- Task execution (tracking control, ...)
- Posture primitives (in particular for humanoids).

To realize consistent behaviors, task hierarchies are constructed such that certain tasks are prioritized over others [69.111]. In [69.112], a hierarchy is realized by null space projection techniques, which also prevents discontinuities concerning unilateral constraints by smoothing out transitions.

Extensions to the basic schemes for flexible joint dynamics [69.113–115] and for the SEA case [69.116] were developed as well. Furthermore, Cartesian impedance control has been applied to grasping and multiple-arm robotic systems in [69.117]. For a more in depth treatment of multipriority impedance control, please also refer to Chap. 67.

69.4.2 Learning and Adaptation

Close physical interaction between human and robot is a complex evolving process with high uncertainty and is hard to be modeled explicitly. Therefore, several learning and adaptation approaches were proposed to enhance a robot's capability and account for the inherently present uncertainty and unpredictability. In this sense, the extension of impedance control toward adaptive controllers that are able to learn and/or adapt the controller's impedance and feed forward torques is a challenging and rather recent research problem. Obviously, also the learning of the desired trajectories, for example, in terms of motion patterns became an important problem in this context. Generally, also collaborative tasks (Sect. 69.4.4) require learning either the impedance properties and/or certain trajectories such that the robot gains the ability to adapt its behavior to the human counterpart, or even guides it to guarantee successful collaboration. An important aspect of learning physical interactions is how to choose the right task coordinates and (meta-)parameters. This is essential to reformulate the otherwise high-dimensional problem spaces in a tractable form.

Since impedance control has already shown to be a valuable technique in cluttered and complex manipulation tasks, recent research focuses on the adaption of the impedance characteristics to further improve the robot capabilities during interaction. Iterative learning control techniques belong to the first methods that have been investigated to tackle difficult manipulation problems [69.118, 119]. However, they do not only require the exact same repetitive motion of the manipulator, but also to account for unforeseen changes in the environment due to force inconsistencies which are particularly present in pHRI. Other early approaches include, for example, the use of neural networks in impedance control to counteract disturbances and environmental uncertainties [69.120]. An approach to adapt force, trajectory, and impedance simultaneously has been presented in [69.121] as a biomimetic controller. It is constructed based on studies in neuroscience that show that humans adapt feedforward and feedback forces as well as their impedance in order to learn unstable tasks in daily life. According to [69.122], the principles of motor learning are:

1. Motor commands to perform a desired action are composed of both feedforward commands, defined as the component of the motor command learned by repeating an activity, and feedback commands.
2. Learning is performed in muscle space.
3. Feedforward increases with the muscle stretch in previous trial.
4. Feedforward also increases with antagonist muscle stretch.
5. Feedforward decreases when the error is small.

Mathematically, these principles can be expressed as follows [69.105]. Generally, the central nervous system tends to minimize the motion error as well as the metabolic cost such that no extra effort will be spent on the learned impedance and feedforward torques. This can be expressed by minimizing the joint-level cost function

$$V(t) = \frac{1}{2} \int_{t-T}^t \tilde{\Phi}^T(\sigma) \mathbf{Q}^{-1} \tilde{\Phi}(\sigma) d\sigma + \frac{1}{2} \epsilon(t)^T \mathbf{M}(q) \epsilon(t). \quad (69.18)$$

Therein, \mathbf{Q} is a positive definite weighting matrix corresponding to the learning rates; $\tilde{\Phi}$ is defined as the difference between the instantaneous value

$$\Phi = [\text{vec}(\mathbf{K}_q(t))^T, \text{vec}(\mathbf{D}_q(t))^T, \tau_{ff}(t)^T]^T \quad (69.19)$$

and the required optimal value Φ^* , that is, $\tilde{\Phi} = \Phi - \Phi^*$. The quantities ϵ , \mathbf{K}_q , \mathbf{D}_q , and τ_{ff} denote the track-

ing control error [69.123] and the values to be learned, namely, the closed loop joint space stiffness, damping, and feed forward motor torques. For the joint stiffness adaption law, this leads for example to

$$\begin{aligned} \delta \mathbf{K}_q(t) &= \mathbf{K}_q(t) - \mathbf{K}_q(t-T) \\ &= \mathbf{Q}_{\mathbf{K}_q} [\epsilon(t) \epsilon(t)^T - \gamma(t) \mathbf{K}_q(t)], \end{aligned} \quad (69.20)$$

where $\gamma(t) > 0$ is a constant forgetting factor and $\mathbf{Q}_{\mathbf{K}}$, which is contained in \mathbf{Q} , is a symmetric positive definite matrix corresponding to the learning rate of the stiffness. T is a time constant to denote task periodicity. In an analog manner, adaption for feedforward torque and damping can be deduced, which results in the following control law,

$$\begin{aligned} \tau_c(t) &= \tau_{ff}(t) - \mathbf{K}_q(t) \epsilon(t) - \mathbf{D}_q(t) \dot{\epsilon}(t) \\ &\quad - \mathbf{L}(t) \epsilon(t) + \tau_r(t) \end{aligned} \quad (69.21)$$

$$\epsilon = \dot{\epsilon}(t) + \kappa \epsilon(t), \quad (69.22)$$

where $\tau_r(t)$ compensates for robot/arm dynamics and bounded noise. The term $\mathbf{L}(t) \epsilon(t)$ ensures a certain stability margin. The overall control law flow chart is depicted in Fig. 69.17. A stability proof of this approach can be found in [69.105]. An open problem with this method that remains to be unsolved is how to automatically select the meta parameters, such as the forgetting factor γ . A similar approach was developed in [69.124], where impedance adaptation laws were tested on a two-robot collaboration task. The robots lift together a beam after a task model was learned. A different approach based on the perturbations of the robot imposed kinesthetically by a human teacher such that the stiffness of the robot is adapted is investigated in [69.125]. Finally, the so-called teleimpedance paradigm [69.126] aims to remotely controlling the robot via the human arm reference position and impedance.

Learning task trajectories has been a rather well-studied field for several years now. For example, in [69.127], the authors examined the task of learning collaborative lifting of an object using hidden Markov models (HMM) and Gaussian mixture regression. Task demonstration was done via a haptic interface that controlled the robot hand. HMMs are also used in [69.128] in order to learn semantic task structures during a joint task execution. A semantic label of recognized task segments is acquired from a human partner by using speech recognition. Tasks in pHRI where transitions from contact to noncontact situations arise have been examined in [69.129]. Therein, marker data is used to obtain motion primitives. These are then updated with contact time information, comprising a low-level layer of learning. In addition, there is a high-level layer, which selects

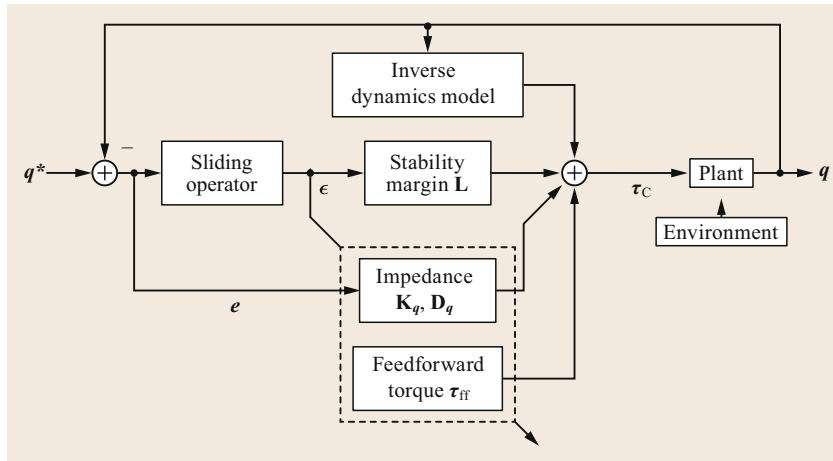

Fig. 69.17 Control diagram of the biomimetic adaptive impedance controller from (after [69.105])

a motion primitive and an end-effector reference position. Again, both layers are encoded via **HMMs** to provide a suitable abstraction, which is a key when dealing with high-dimensional spaces.

In [69.17], dimensionality reduction for learning was employed to realize assistive tasks, such as helping a robot to stand-up or walk. This principal component analysis (**PCA**)-based reduction lets the learning take place in a low-dimensional joint manifold instead of the original high-dimensional space. It reduces the complexity of the learning domain for multidegree-of-freedom systems such as humanoids. A recent approach to learning trajectories based on human preferences was proposed in [69.130], where machine-learning techniques were applied to derive the optimal behavior from human action ratings during runtime. Figure 69.18 shows how the robot learns to handle a knife safer by receiving low rewards from the human if the dangerous tool is moved in undesired orientations and/or trajectories.

69.4.3 Collision Handling

One of the core problems in **pHRI** is the handling of collisions between robots and humans, with the primary motivation of limiting possible human injury due to physical contacts. Various *monitoring signals* can be

used to gather context independent information about the event.

The *collision detection phase*, whose binary output denotes whether a robot collision occurred or not, is characterized by the transmission of contact wrenches, often for very short impact durations. The occurrence of a collision, which may happen anywhere along the robot structure, shall be detected as fast as possible. A major practical problem is the selection of a threshold on the monitoring signals, so as to avoid false positives and achieve high sensitivity at the same time. A heuristic approach is to monitor the measured currents in robot electrical drives, looking for fast transients possibly caused by a collision [69.131, 132]. Another proposed scheme compares the actual commanded torques (or motor currents) with the nominal model-based control law (i.e., the instantaneous torque expected in the absence of collision), with any difference being attributed to a collision [69.133]. This idea has been refined by considering the use of an adaptive compliance control [69.134, 135]. However, tuning of collision detection thresholds in these schemes is difficult because of the highly varying dynamic characteristics of the control torques.

Knowing which robot part (e.g., which link of a serial manipulator) is involved in the collision is an important information that can be exploited for robot

Fig. 69.18 The robot Baxter learns to safely handle a knife ([69.130]; courtesy of Saxena's Robot Learning Lab)

reaction. *Collision isolation* aims at localizing the contact point \mathbf{x}_c , or at least which link i_c out of the n -body robot collided. One way to obtain both collision detection and isolation is to use sensitive skins [69.91–94]. However, it would obviously be more practical and reliable to detect and possibly isolate a collision without the need of additional tactile sensors. On the other hand, the previously mentioned monitoring signals used in [69.131–135] are in general not able to achieve reliable collision isolation (even when robot dynamics is perfectly known). In fact, they either rely on computations based only on the nominal desired trajectory, or compute joint accelerations by inverting the mass matrix and thus spreading the dynamic effects of collision on a single link, or use acceleration estimates for torque prediction and comparison, which inherently introduces noise (due to double numerical differentiation of position data) and intrinsic delays. The common drawback of these methods is that the effect of a collision on a link propagates to other link variables or joint commands due to robot dynamic couplings, thus affecting the isolation property.

Other relevant quantities about a collision that are deduced during the *collision identification phase* are the directional information and the intensity of the generalized collision force, either in terms of the acting Cartesian wrench $\mathcal{F}_{\text{ext}}(t)$ at the contact, or of the resulting joint torque $\boldsymbol{\tau}_{\text{ext}}(t)$ during the entire physical interaction event. This information characterizes (in some cases, completely) the collision event. The first method that simultaneously achieved collision detection, isolation, and identification was proposed in [69.136]. The basic idea was to view collisions as faulty behaviors of the robot actuating system, while the detector design took advantage of the decoupling property of the robot *generalized momentum* $\mathbf{p} = \mathbf{M}(\mathbf{q})\dot{\mathbf{q}}$ [69.137, 138].

During the *collision reaction phase*, the robot should react purposefully in response to a collision event, that is, taking into account available contextual information. Because of the fast dynamics and high uncertainty of the problem, the robot reaction should be embedded in the lowest control level. For instance, the simplest reaction to a collision is to stop the robot. However, this may possibly lead to inconvenient situations, where the robot is unnaturally constraining or blocking the human [69.19]. To define better reaction strategies, information from collision isolation, identification and classification phases should be used. Some examples of successful collision reaction strategies have been given in [69.87, 139].

Collision Detection and Identification

A recent overview on standard techniques to estimate $\boldsymbol{\tau}_{\text{ext}}$ can be found in [69.26]. In this chapter,

we focus on the main method, namely the monitoring method based on the observation of the generalized momentum that was introduced in [69.136]. The scheme, which is regarded as the standard algorithm, was motivated by the desire of avoiding the inversion of the robot inertia matrix, decoupling the estimation result, and also eliminating the need of an estimate of joint accelerations. The according disturbance observer-based estimator for the rigid case is defined as

$$\mathbf{r}(t) = \mathbf{K}_O \left\{ \hat{\mathbf{p}}(t) - \int_0^t [\boldsymbol{\tau} - \hat{\boldsymbol{\beta}}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{r}] ds - \hat{\mathbf{p}}(0) \right\}, \quad (69.23)$$

with $\hat{\mathbf{p}} = \hat{\mathbf{M}}(\mathbf{q})\dot{\mathbf{q}}$, $\hat{\boldsymbol{\beta}}(\mathbf{q}, \dot{\mathbf{q}}) = \hat{\mathbf{g}}(\mathbf{q}) + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} - \hat{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}}$, and $\mathbf{K}_O = \text{diag}(k_{O,i}) > 0$ being the diagonal gain matrix of the observer. Under ideal conditions, $\hat{\mathbf{M}} = \mathbf{M}$ and $\hat{\boldsymbol{\beta}} = \boldsymbol{\beta}$, the dynamic relation between the external torque $\boldsymbol{\tau}_{\text{ext}}$ and \mathbf{r} is

$$\dot{\mathbf{r}} = \mathbf{K}_O(\boldsymbol{\tau}_{\text{ext}} - \mathbf{r}). \quad (69.24)$$

In other words, \mathbf{r} is a stable, linear, decoupled, first-order estimation of the external collision torque $\boldsymbol{\tau}_{\text{ext}}$. Large values of $k_{O,i}$ give small time constants $T_{O,i} = 1/k_{O,i}$ in the transient response of that component of \mathbf{r} , which is associated with the same component of the external joint torque $\boldsymbol{\tau}_{\text{ext}}$. In the limit, we obtain

$$\mathbf{K}_O \rightarrow \infty \Rightarrow \mathbf{r} \approx \boldsymbol{\tau}_{\text{ext}}. \quad (69.25)$$

Collision Reflex Reactions

After a collision has been detected, suitable collision reflex reaction is needed. Four basic context-independent joint-level collision reflexes are discussed next. They lead to significantly different reflex behavior after a contact was detected. In the third and fourth schemes, the directional information on contact torques provided by suitable identification schemes such as (69.23) may be used to safely drive the robot away from the collision location.

Robot Stop. The most obvious strategy to react to a collision is to stop the robot. This behavior can, for example, be obtained by setting $\mathbf{q}_d = \mathbf{q}(t_c)$, where t_c is the instant of collision detection or by simply engaging the robot's brakes. More elaborate braking strategies can be found in [69.140].

Torque Control with Gravity Compensation. One may also react to a collision by switching the controllers. Typically, prior to the collision incident, the

robot moves along a desired trajectory with a position reference-based controller (e.g., position or impedance control). After detection, the control mode is switched to a compliance-based controller that ignores the previous task trajectory. A particularly useful variant is to switch to torque control mode with gravity compensation $\tau = \hat{g}(q)$ (VIDEO 611). Note that this strategy does not explicitly take into account any information about τ_{ext} .

Torque Reflex. This strategy extends the torque control-based strategy by explicitly incorporating the estimation or measurement of τ_{ext} into the motor torque τ via

$$\tau = \hat{g}(q) + (\mathbf{I} - \mathbf{K}_r)\tau_{\text{ext}}, \quad (69.26)$$

where $\mathbf{K}_r = \text{diag}\{k_{r,i}\} > 1$. It can be shown that, under sufficiently accurate estimates or measurements, such a law is equivalent to scaling of the robot dynamics by \mathbf{K}_r^{-1} . The closed-loop dynamics become

$$\underbrace{\mathbf{K}_r^{-1}\mathbf{M}(q)}_{\mathbf{M}'(q)}\ddot{q} + \mathbf{K}_r^{-1}\mathbf{C}(q, \dot{q})\dot{q} + \tau_{\text{ext}} = \mathbf{0}, \quad (69.27)$$

where $\mathbf{M}(q) > \mathbf{M}'(q)$ holds component-wise.

Admittance Reflex. Reference trajectory modification via an admittance-type strategy that uses the measurement or estimation of τ_{ext} can easily, for example, be realized via

$$q_d(t) = - \int_{t_c}^T \mathbf{K}_a \tau_{\text{ext}} dt, \quad (69.28)$$

where $\mathbf{K}_a = \text{diag}\{k_{a,i}\} > 1$. With this scheme that requires no control switching the robot quickly drives away from the external torque source and decreases the contact forces till they decay to zero.

69.4.4 Shared Manipulation Control

Collaborative carrying, particularly of a long, large, heavy or flexible object, is a common scenario in pHRI research (Fig. 69.19). As discussed earlier, Cobots represent the parallel case where passive robotic devices control the path along which a shared load will be transported, but give their operator full control of load motion along that path (Chaps. 39 and 70; VIDEO 821). Most shared manipulation schemes utilize some form of impedance control [69.142]. In an early work, the authors of [69.143, 144] proposed an impedance controller with speed-dependent damping coefficients. The

authors of [69.145] employed a similar approach (with fixed virtual impedance) to control the horizontal movement of their Mobile Robot Helper's mobile base in response to applied forces of a human user on the other end of a cooperatively carried load (VIDEO 606). The authors of [69.144] also described a lifting controller employing a pair of cascaded second-order virtual admittance controllers. Due to the raising/lowering of a cooperatively carried load the applied torques on an admittance-controlled, high-stiffness wrist generate a wrist deflection that translated (via a fixed gain) into a virtual vertical force. This force raised or lowered the robot end effector via a second admittance controller. In [69.141], an admittance controller was presented that was tuned for human preference, which is typically slightly underdamped. In [69.146], an admittance strategy was used to translate user force input into robot steering commands within a constrained trajectory.

Ideally, in cooperative manipulation, robotic and human partners will naturally take turns with leading and following roles depending on the state of a shared task. A switching model for haptically linked human-robot pairs that allows the robot to continuously vary its behavior from *completely following* to *completely leading* was introduced in [69.16]. In [69.147], the authors presented a mathematical treatment of the cooperative load manipulation problem to allow one or more robots to carry a load with a human user along a desired trajectory. They also incorporated variable leading behavior in the robots, enabling them to just steer the load (following) or completely control the load's axial motion (leading).

More recently, Evrard's homotopy approach was applied to load lifting, enabling the robot assistant to vary its behavior between leading and following based on its confidence in its predictions of the human user's

Fig. 69.19 Collaborative lifting experiment with a long object (after [69.141])

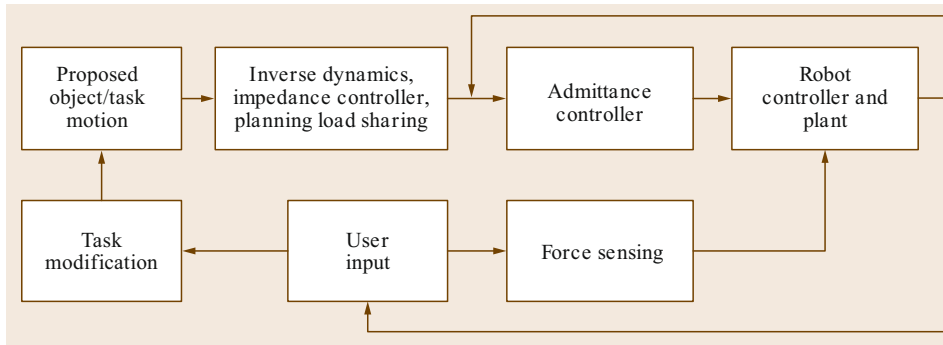

Fig. 69.20
Generalized

control

intentions [69.15] (VIDEO 617). These are monitored through the kinematics of the shared load. Recently, an admittance control law that guarantees the stability of the robot during constrained motion and also provides a quite intuitive human interaction was designed in [69.148]. The admittance law uses the time derivative of the contact force between the human and the robot to estimate human intent and an online estimate of the interaction stiffness resulting in very accurate shared-control of the robot system. In [69.149], the authors developed and user tested an interactive controller

for a collaborative carrying task, utilizing a strategy to model effort sharing between the robot and the user. A generalized schematic for admittance-based collaborative task control is depicted in Fig. 69.20. On the motion planning side, minimum jerk trajectories [69.150] have been used to generate robot trajectories that are well matched to the motion of the human partner, and require the human to use less energy in the interaction, for example, [69.151]. Results from [69.152] indicate that a simpler quintic trajectory was also suitable for this purpose.

69.5 Motion Planning for Human Environments

The definition and quantification of injury, pain, or general risk are essential to express what safe behavior really means. The according insights can also be applied to generate safer robot motions such that injury and risk prevention are explicitly taken into account at this level. Two main branches of motion planning algorithms for danger reduction were developed, which are described hereafter.

69.5.1 Biomechanically Safe Motion Planning

As mentioned in the beginning of the chapter, human collision safety has to be ensured from an injury biomechanics perspective. Safety could, for example, be defined as *ensuring that only mild contusions may occur in worst case scenarios*. The natural question that arises is now how to formally respect such a metric, that is, how should a robot be controlled so that an unforeseen contact remains subcritical according to the underlying injury biomechanics or pain data. For this the authors of [69.25] gave the schema, termed safe motion unit (SMU), to link basic data to intrinsically safe robot velocity. The basic idea is to represent any data or general insight in a (possibly purely data driven) functional relation, linking impact properties to human

injury or pain. With this, it is possible to calculate the instantaneous safe robot velocity given the robot's inertial properties, surface curvature, and possible human body parts it might collide with

$$\begin{aligned} &(\text{mass, velocity, geometry, body part}) \\ &\rightarrow \text{observed injury/pain} . \end{aligned} \quad (69.29)$$

For the injury/pain metric, multiple international classifications exist from which one may choose from. In [69.25], for example, the AO-classification was used. Thereafter, a careful set of experiments, or if possible simulations, can be generated to deduce the relation of interest. Each experiment should be designed such that the impacting mass, its velocity, and curvature are known in addition to any supplementary sensory readings of interest. Furthermore, the observed, measured, or calculated injury and/or pain level of the involved body part has to be quantified according to the selected scale. To restrict the amount of experiments to a feasible number, the impactor geometry is assumed to be composed of different basic geometric primitives (spheres, cuboids, corners). Thus, a finite set of so-called *safety curves* can be constructed, which represent fitted threshold curves for a given injury indicator in

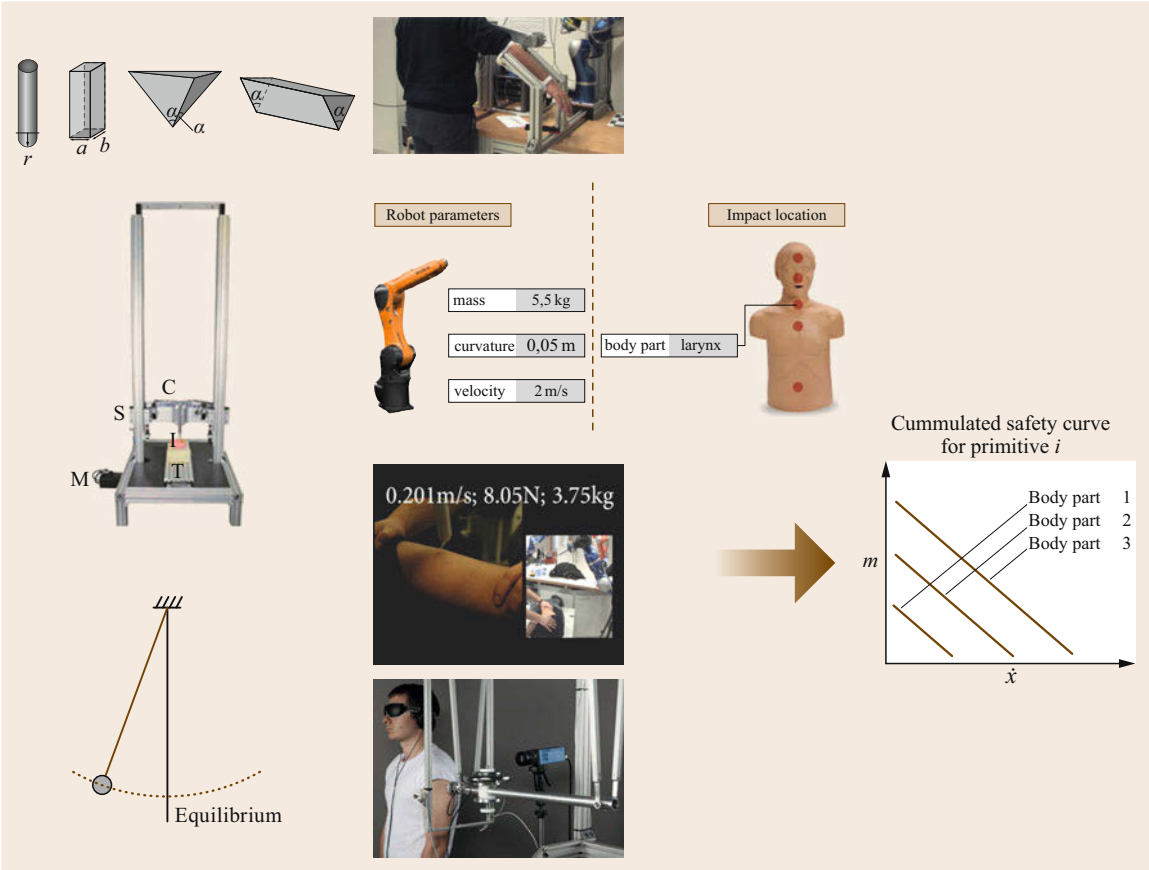

Fig. 69.21 A unified view: From collision experiment/simulation to cumulative *safety curves* for biomechanically safe robot velocity

the mass–velocity space parameterized by the body part (Fig. 69.21).

This idea can now be applied to a robot for safe velocity generation (Fig. 69.22). The concept is to scale any desired velocity command \dot{q}_d by α to a biomechanically safe value \dot{q}_d^* . The scalar α is computed from evaluating the instantaneous robot inertial and local surface properties with respect to their injury potential. For this, the effective mass m_{POI} in the respective u -directions of the relevant points of interest (POIs) are

ically safe value \dot{q}_d^* . The scalar α is computed from evaluating the instantaneous robot inertial and local surface properties with respect to their injury potential. For this, the effective mass m_{POI} in the respective u -directions of the relevant points of interest (POIs) are

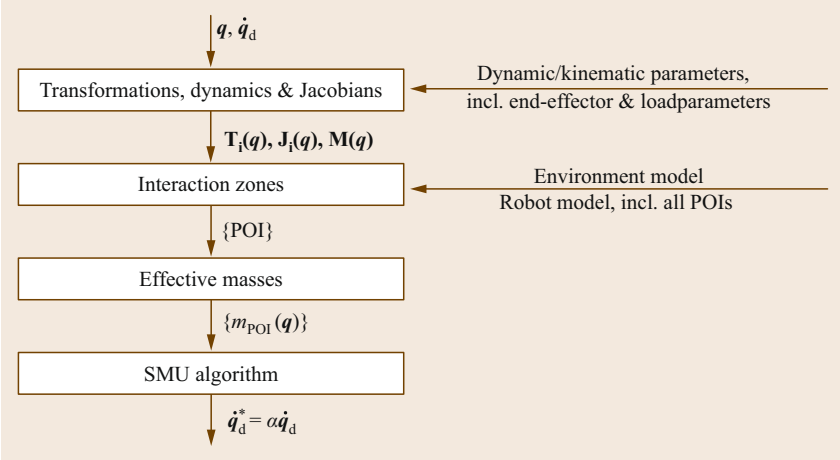

Fig. 69.22 Pipeline for creating biomechanically safe velocities based on the SMU algorithm (after [69.25])

evaluated via (69.7). Each POI is associated with a surface geometry primitive that is then used to link the respective POI to some underlying biomechanical injury, pain, or risk *safety curve*.

69.5.2 Risk–Metric–Based Motion Planning

As discussed in Sect. 69.4.3, there are numerous techniques for detecting impacts or potential collisions during pHRI. Collision monitoring methods can be used to ensure that forces and torques, or more simply the energy, of the robot system are limited during a collision event. To ensure safe and human-friendly interaction in unstructured environments, additional safety measures, utilizing system control, and planning are required.

Since physical interaction itself is a collision, a key problem of human-safe planning and control methods is to identify when human safety is actually threatened. In [69.154], a danger evaluation method was developed using the potential impact force as an evaluation measure. In this work, several danger indices were proposed based on the design properties of the robot. This danger index can be defined as a product of factors which affect the potential impact force between the robot and the human, such as distance, relative velocity, robot inertia, and robot stiffness. The authors applied this index as an objective function for improved mechanical design, control, and motion planning. A danger index based on estimated impact forces for a potential collision between a robot and a human was computed in [69.155] and used as an input to a real-time trajectory generation system, which balances the goal seeking with potential danger. In [69.153], the same authors combined their system with a vision based and physiological monitor-

ing system, which allows the robot to respond to the user's real-time position and attentiveness. During the interaction, the user is monitored to assess his level of approval of the robot's actions while the trajectory planner monitors safety factors, such as robot velocity and user intent. Finally, the safety control module provides a real-time response to short-term horizon factors evaluated by a *safety measure estimation module* (Fig. 69.23).

For mobile service robots, the authors of [69.156] proposed a collision avoidance controller based on estimates of user behavior, using a *social force* model to determine whether the user intends to avoid the collision or not so that the robot can respond accordingly. In [69.157], the authors introduced a method using so-called kinetostatic danger fields as a metric for the danger which the current posture and velocity of a robot pose to objects in its environment. The work presented in [69.121] shows an algorithm which maximizes the productivity of an industrial robotic manipulator while guaranteeing a safe human–robot distance. In addition to the relative human–robot distance, it takes also dynamic and control characteristics into account. In [69.158], the authors proposed a method based on an intuitive physical interpretation, namely, an impedance-like second-order motion generation. It is designed to provide safe motion in complex environments, taking into account both proximity to objects, and external forces. A method that achieves collision avoidance for a redundant robot while permitting the end-effector task to continue is presented in [69.159]. Using data from a 3-D-RGB-D camera, this method is purely based on computations of distances between the robot body and dynamic obstacles in the workspace (e.g., the user) that are processed through a *risk function* to adjust the joint

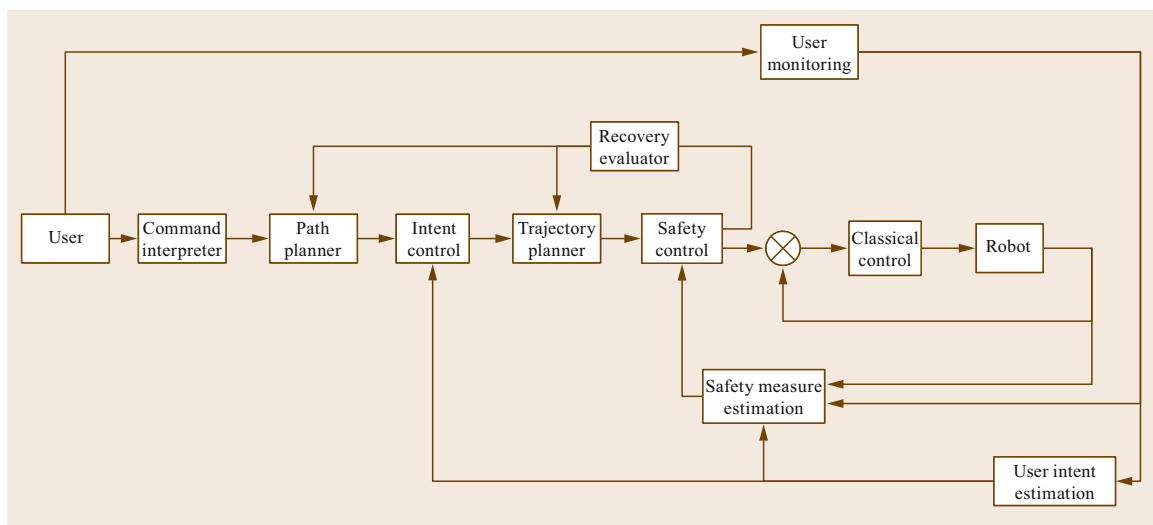

Fig. 69.23 Schematic of motion planning system with user intent and safety monitoring input (after [69.153])

Fig. 69.24 Human-aware motion planner of Laboratoire d'analyse et d'architectures des systèmes (LAAS) (after [69.160]; courtesy of Rachid Alami)

velocities. The motion task of the end effector is modified by an artificial potential field-type method.

69.6 Interaction Planning

In order to profit from the collaboration of human and robot by combining the flexibility, knowledge and sensory skills of a human with the efficiency, strength, endurance, and accuracy of a robot, according interaction planners need to be designed to plan their joint actions for a common goal. In the interaction planning domain, the central question is how to plan robot human joint actions and reactions in a certain interaction process, involving also unexpected environmental changes, one of the most basic ones being the human entering the robot's workspace. The definition of the interaction planning problem and the integration of reflex reaction schemes that potentially lead to an abrupt deviation from nominal course have to be elaborated. On an architectural level, the incorporation of *reactivity* has to be systematically represented.

69.6.1 Collaborative Action Planning

Approaches to subproblems of the full interaction planning problem were addressed in the literature. In [69.163], for example, the system SHARY for human-aware task planning was introduced. It produces social plans of a task by implementing communication schemes to negotiate the task solution with the human partner.

In [69.164], dynamic neural fields (DNFs) were used to build a decision-making system for interac-

69.5.3 Human-Aware Motion Planning

Applying and extending classical motion planning techniques to the problem of human-robot interaction was originally done in [69.160]. The authors developed a human aware mobile robot motion planner, which incorporates humans accessibility, their vision field, and their preferences in terms of relative human-robot placement (Fig. 69.24). Human dynamics were integrated into the algorithm.

Extensions of the original work toward a motion planner for pHRI scenarios were elaborated in [69.161]. Therein, certain constraints, such as distance, visibility, and comfort are taken into account to generate safer motions and were demonstrated within a handover scenario. The algorithm has been extended to cluttered environments in [69.162], where a randomized cost-based exploration method provides an initial path that is relevant with respect to pHRI and workspace constraints.

tion in cooperative human-robot tasks. The main idea is to let the robot imitate human behavior in order to make the cooperation between robot and human appear rather intuitive. A structural overview of the system is depicted in Fig. 69.25. A vision system observes the scenery and recognizes task-related objects and gestures of the human coactor. Object positions are stored in the *object memory layer*. The *action observation layer* decides which type of known action was executed by the coactor. The expected outcome of this action is then simulated by the *action simulation layer* and thereafter passed to the *intention layer*. Here, the intention of the coactor is determined. The knowledge about the coactor's intention and the expected outcome of his actions is used by the *common subgoal layer*. It contains prior knowledge about the task structure and the subgoals to be achieved for task completion. The *common subgoal layer* is responsible for enabling actions that lead to the fulfillment of a currently achievable subtask only. Based on the information coming from the *intention layer* and the *object memory layer*, the *action execution layer* decides to perform an action, which supports the human in the intended subtask or leads to the completion of an independent subtask and does not interfere with the current human intention. Each layer of the system is formalized by one or more DNFs. The activity $u_i(x, t)$ at time t of a neuron x is described by the differential

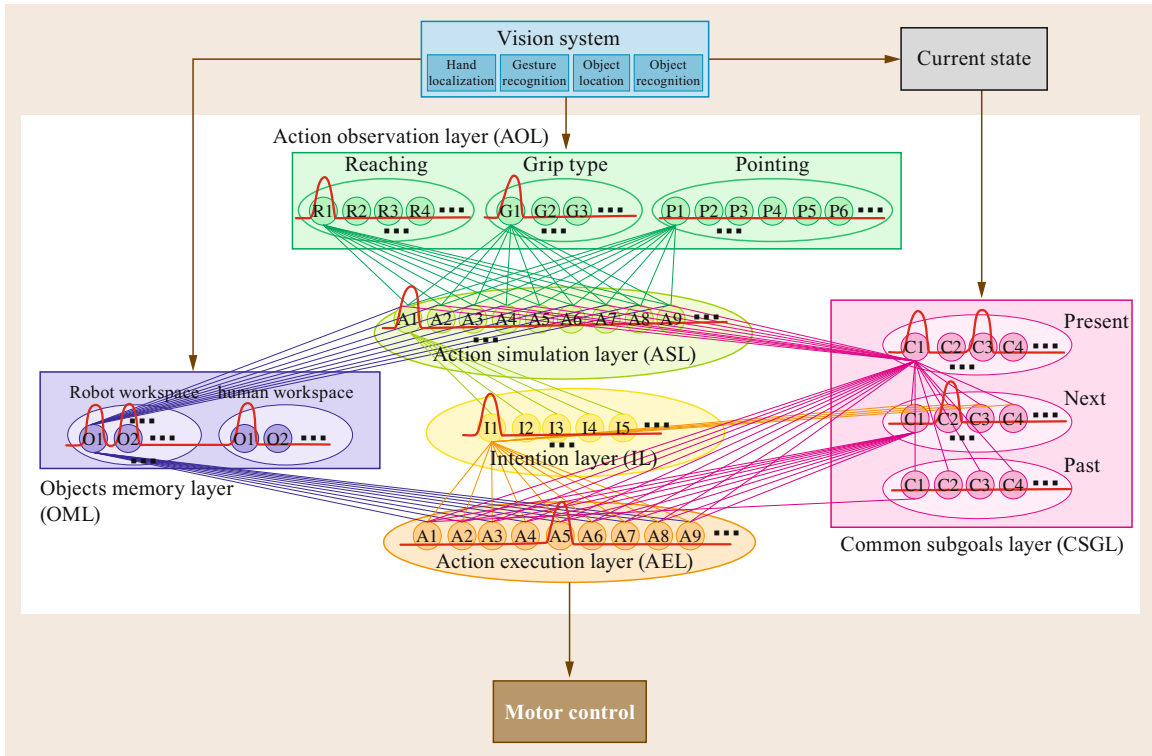

Fig. 69.25 Structural overview of the decision-making system from (after [69.164]; courtesy of Estella Bicho)

equation

$$\tau_i \frac{\delta u_i(x, t)}{\delta t} = -u_i(x, t) + S_i(x, t) + \int w_i(x - x') f_i(u_i(x', t)) dx' - h_i, \quad (69.30)$$

where $\tau_i > 0$ and $h_i > 0$ denote the timescale and the resting level of the field dynamics, respectively. S_i is the summed input to a local population. The output function f_i is chosen to be a sigmoid function and the interaction strength $w_i(x - x')$ is a Gaussian curve, which depends only on the distance between x and x' (Fig. 69.26).

In [69.129], a mimetic communication model for pHRI is introduced, where the according motion primitives are taught by human demonstration via marker control. These are subsequently encoded into hidden Markov models (HMMs) and allow the robot to execute them and even to recognize the motion primitives executed by the human partner. Based on the motion primitives, interaction primitives are then learned as chains of actions and reactions. The flow of interaction primitive learning is depicted in Fig. 69.27a. First, the robot executes a motion primitive, followed by ob-

serving the human's respective reaction in order to learn the correct interaction pattern sequence. After this step, the motion primitives are updated and the process is repeated. The underlying scheme of interaction is shown in Fig. 69.27b. The learned motion primitives are encoded as continuous HMMs (CHMMs) and form the middle layer of the system. They are then used to recognize the motion primitive executed by

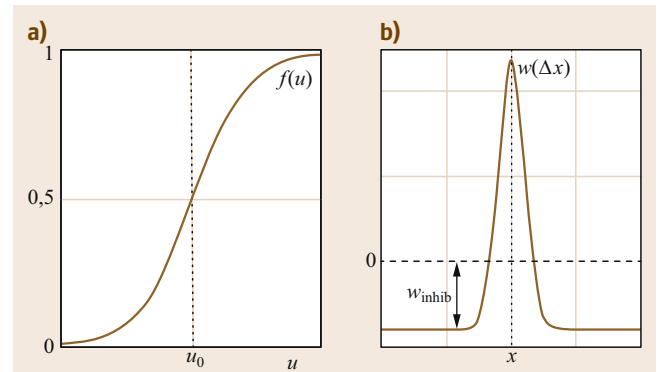

Fig. 69.26 (a) Nonlinear threshold output function that maps activity to a sigmoidal with threshold u_0 . (b) Synaptic weight function for modeling the interaction strength between any two neurons x and x' in (69.30) (after [69.164]; courtesy of Estella Bicho)

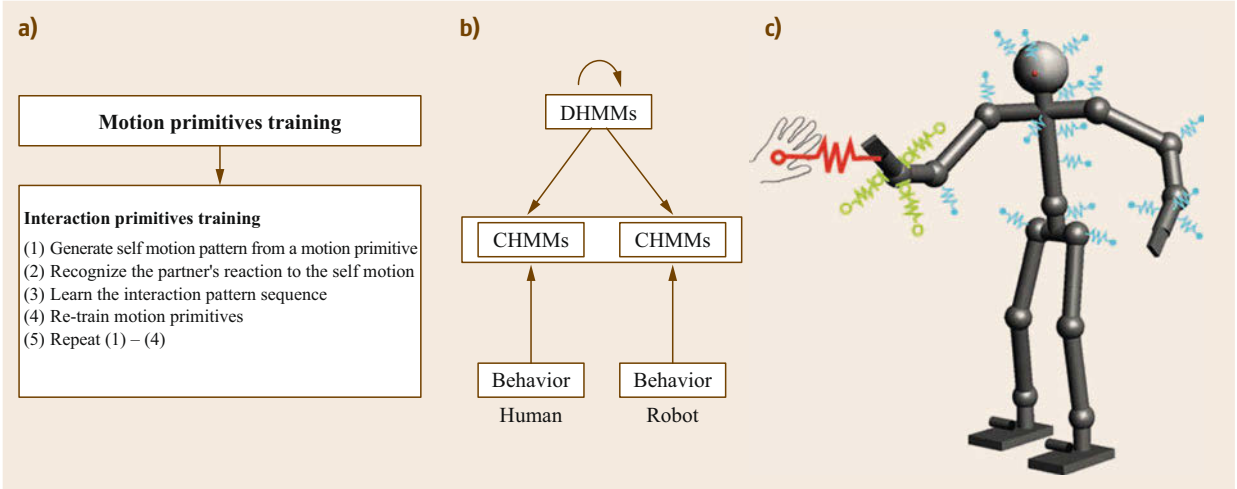

Fig. 69.27 (a) Learning of interaction primitives. (b) Scheme of interaction. (c) Adaption of robot motion via virtual spring (after [69.129]; courtesy of Dongheui Lee)

the human and to generate the motion of the robot according to the interaction primitives encoded as discrete **HMMs** (**DHMMs**) at the top. The robot motion (more precisely its behavior in the context of the authors' work) may then be modified to adapt to human motion in the real world (expressed by the thin horizontal arrow). The bold horizontal arrow represents the assumed adaption of the human to the robot behavior. The adaptation strategy of the robot movement is depicted in Fig. 69.27c. For this, an impedance controller is used in combination with a virtual spring connected to the robot hand to attract the device into the correct position. Figure 69.28 depicts an application of the interaction scheme, where the robot high- or low-fives a human coactor with one or two hands, respectively.

69.6.2 Interaction Planning Problem

In order to formalize the interaction planning problem, one needs to be able to describe the entire scenario, the system state of the robot, the state of the human(s) (possibly including future behavior prediction of both), the environment state including all relevant objects and the overall abstract task state. This information about the world state comprises the concept of an *interaction*

world, which builds the basis for formulating the general *interaction planning problem*.

Definitions

The set of *world states* **WS** is defined as

$$\mathbf{WS} = \mathbf{RS} \times \mathbf{HS}^n \times \mathbf{OBS}^m \times \mathbf{TS}, \quad (69.31)$$

where **RS**, **HS**, **OBS**, **TS** denote the set of the robot states, n humans, m obstacles, and an overall task state, respectively.

The set of *robot states*

$$\mathbf{RS} = \mathbf{S} \times \mathbf{RA}^n \times \mathbf{IR} \quad (69.32)$$

contains information about the internal state $s \in \mathbf{S}$ of the robot, the robot awareness $ra \in \mathbf{RA}$, and the interaction state $ir \in \mathbf{IR}$. The interaction state of the robot may, for example, take the values *autonomous*, *collaborative*, or *cooperative*. The robot awareness indicates its ability to predict human actions. The set of internal states $\mathbf{S} = \mathbf{S}_{ac} \times \mathbf{S}_b \times \mathbf{S}_p$ contains information about the set of actions carried out by the robot \mathbf{S}_{ac} . Furthermore, the behavior set \mathbf{S}_b , which includes, for example, controller choices and respective parameterizations, reflex reactions, and type or parameterizations of trajectory

Fig. 69.28 pHRI using the mimetic communication model (after [69.129]; VIDEO 625; courtesy of Dongheui Lee)

planners. Such a reflex reaction which can be thought of as an analogy to human reflexes, intends to bring the robot to a safe state or even a reflex cascade R (Sect. 69.6.3). Finally, the physical state $sp \in S_p$ contains, for example, the robot's instantaneous position, velocity, and momentum.

The set of *human states*

$$HS = PSH \times PA \times HA \times IH \times D \quad (69.33)$$

combines the sets of physical state PSH (position, velocity, etc.), personal attributes PA (fitness, age, experience, etc.), human awareness HA (the ability of the human to predict the robots actions), interaction states of the human IH (for example, *waiting for robot*, *work with robot* or *work without robot*), and the distances D between human and robot. In its most simple nontrivial case, D could, for example, consist of the elements *in workspace*, *in perception*, *out of perception*, and *lost perception*.

The set of *task states*

$$TS = A \times TC \times IS \quad (69.34)$$

contains A , TC , IS that denote the sets of possible actions, task criticality, and expected interaction between human and robot, respectively. The task criticality specifies the effect of potential task failure on human safety. A task consists of the meaningful composition of actions and/or more complex skills such as *grasp object* or simply *move to pose* according to a particular creation process.

The Interaction Planning Problem

The *interaction planning problem* then denotes the problem of selecting a suitable, and if possible optimal, robot action and associated behavior in every time step based on the information contained in the world state, the history of the process HIS , and available (dynamic) knowledge stored in a knowledge base KB (for example, safety knowledge, object properties, world grounding rules, ...). Formally, this can be expressed by the *select action mapping*

$$sa : WS \times HIS \times KB \rightarrow S_{ac} \times S_b. \quad (69.35)$$

Optimality could, for example, be expressed in the following *reinforcement learning* sense, where the selected behavior shall lead to a maximum reward. This is obtained as follows:

1. A *task evaluator* evaluates the suitability of a particular action/behavior for fulfilling the desired task.
2. A *safety evaluator* evaluates the overall safety of the situation by taking into account different biomechanical injury criteria, the expected interaction

between human and robot, human–robot–related geometric quantities, such as minimal distance, as well as the task criticality.

3. Finally, additional rewards may be given by the human in order to capture human-friendly behavior.
4. The overall reward is then a suitable combination of the basic rewards.

69.6.3 Robot Reflexes

Human reflexes are involuntary reactive body movements in response to a perceived input, the so-called stimulus, that is, one does not even have to *think about what to do*. In humans, reflexes aim for body protection. Based on built-in heuristics, they automatically protect the human body from injury. However, the exact separation in terms of hybrid system-like theory is not yet clear. Thus, the line between discrete reflex states and according systemic responses on both electrical and mechanical levels is somewhat blurred. In robotics, on the other hand, it is possible to separate these levels and extend the concept of basic *nominal robot actions* by *reflex reactions* [69.9, 85, 139]. These concepts systematically incorporate the possibilities one gains from the already described collision detection and reflex reaction schemes (Sect. 69.4.3). Other work in similar directions for developing human-like withdrawal reflexes can be found in [69.165].

In contrast to the classical planning and execution pipeline, the activation of reflexes that are able to override the nominal task plan due to environmental or internal conditions that do not comply with nominal task behavior have to be considered. In contrast to humans, these reflexes do not necessarily have to be fixed (or slowly time-varying over learning cycles). On the contrary, they may be tailored to every nominal action such that local context dependency (in particular instantaneous sensory input) may be taken into account. After instantaneous reactions are executed, the main problem is to decide what to do next. Either local re-entry into the previous plan or entire re-planning have to be executed. Figure 69.29 depicts the overall concept also in the context of task and interaction planning.

Formally, a robot reflex is associated with a suitable activation signal. Typically, this represents either the indication of a certain stimulus or a fault. Stimuli are general perception inputs, whereas faults are detected either by processed stimuli (observation of external torques, proximity information, etc.) or general system malfunctions as, e.g., communication collapse or runtime violations. Even rather complex reflex patterns can be activated that may be represented as directed reflex graphs, i.e., a decisional component in the inner most

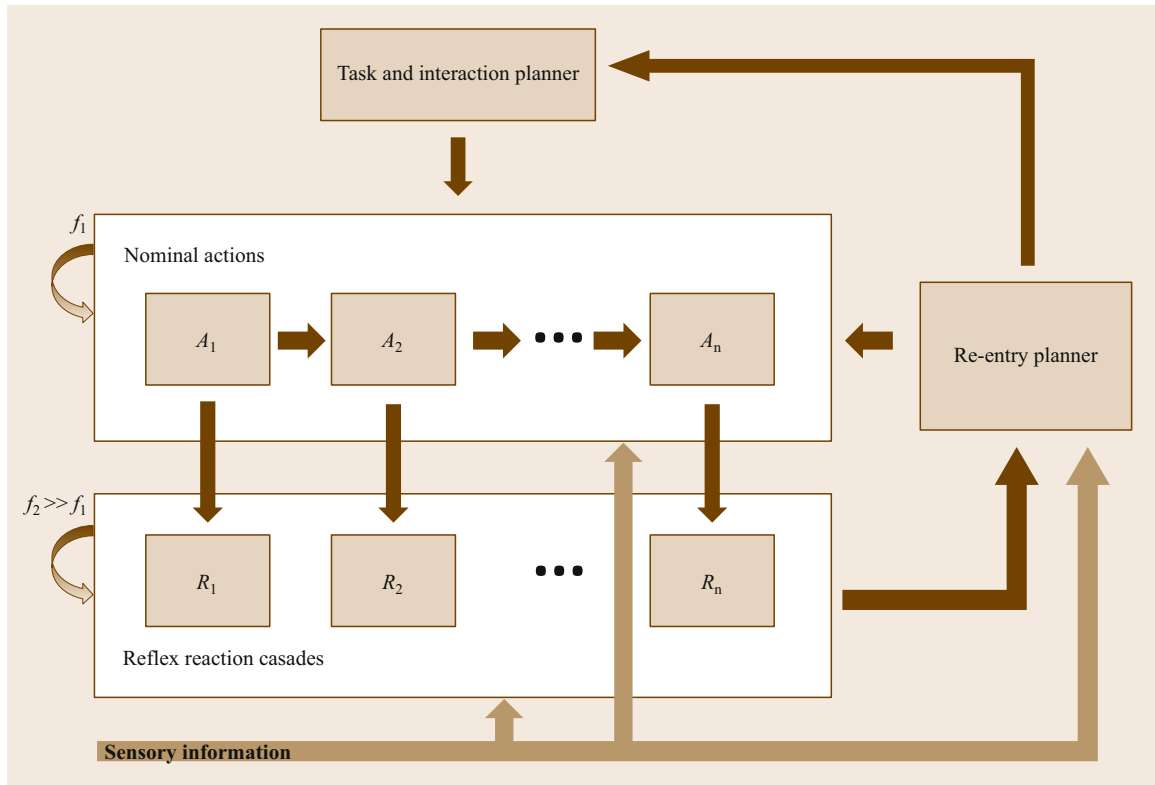

Fig. 69.29 Conceptual sketch of robot reflexes; f_1 and f_2 indicate the update rates, or alternatively the system bandwidth of the nominal planning and execution as well as the reflex reaction level. Typically, the former acts at a much lower frequency than the latter one (after [69.85, 139])

control loop of the system. A still relatively open research problem is how to resolve potential failures after reflexes were triggered by planning suitable re-entering and continuation of the task.

69.6.4 Reactive Control Architecture

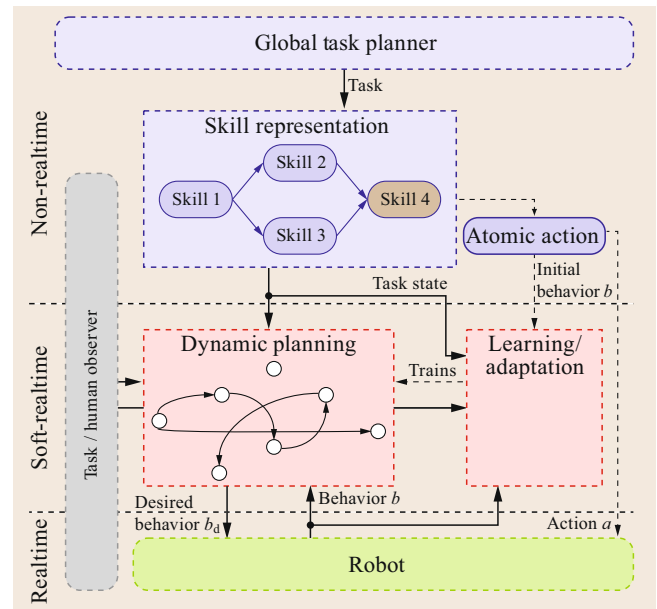

Obviously, the diverse methods and complex requirements in the pHRI domain and more specifically from interaction control, reflex planning, human-centered motion planning, and interaction planning make new architectural concepts necessary. The central requirements to an according control architecture become rather different from the classical ones (Chap. 12) due to the demands for very responsive behavior not only on control but also on planning level. Figure 69.30 depicts such a reactive control framework [69.166] (VIDEO 616). One of the main questions to address is how to adapt dynamically, safe, and task consistent, while keeping the overall plan and the respective context in mind. The control framework is composed of three layers of abstraction operating at different time scales:

1. On the highest level of abstraction a *global task planning* module builds global task plans that contain temporo-logical concatenations of robot skills, which are derived from any suitable task planning language. Typically, this module runs either offline, in particular when building an entire nominal task plan that contains interaction schemata, or at very slow update rates of several seconds or minutes, depending on the complexity and novelty of the respective task. Skills are topologically invariant capability structures, which instantiations can be modified in terms of skill parameter vectors. The most basic skill is the atomic robot action that represents the formal interface to the robot real-time control core and mechatronics. More complex skills can, e.g., be *grasp an object* or *hand over an object*. Each skill itself is aware of the current task state and which atomic action is currently being executed. This information is then sent to the *dynamic planning layer*.
2. The second layer of abstraction, the *dynamic planning level* is capable of executing and/or modifying plans dynamically, which means that it shall run at least in the range of $\approx 1\text{--}10\text{ Hz}$. It is responsible

Fig. 69.30 Reactive and human-friendly control framework for acting in partially known environments and interaction ►

for selecting the best action under the premise of the current task state, human state and behavior, as well as the environmental state. In a *learning and adaptation* unit the global task knowledge is translated into the respective dynamic planning domain language, i. e., global knowledge and plans are encoded into a dynamic level such that dynamic adaptation can make use of global context and the respective mission. The according reactive planning unit is then able to (re-)plan the robot's desired nominal actions such that safe, yet task consistent actions, are executed if possible. In particular, instantaneous perception may cause alterations of the original global plans. A major task on this abstraction level is to change the preplanned course of action safely and task consistently. However, finding its way back into the task is at least equally challenging and requires careful treatment (re-entry planning).

3. The lowest architectural layer is the *low-level (real-time) control layer*. Typically, this is subdivided into multiple hierarchical layers, involving also the reflex machine (Fig. 69.29). However, for sake of clarity, we consider it to be a single consistent representation that is accessible via a desired action/behavior complex (a_d, b_d) that is sent to the system for execution. As the desired behavior may alter due to reflex behaviors in case of accidental events such as unforeseen collisions, the control

layer feeds back the currently active action/behavior pair (a, b), such that the *dynamic planning layer* is able to react accordingly.

Fundamental to the aforementioned architecture is the capacity to observe human actions on various levels of abstraction. In this sense, a *human observer* that gathers all relevant information and knowledge about human agents is essential. In particular, it provides human-related information that can be of further use.

69.7 Conclusions and Challenges

pHRI has become a central discipline in robotics over the last decade. This is due to the significant progress made in the fields of mechatronics, interaction control, motion planning, and 3-D sensing toward highly integrated and sensorized lightweight systems that are able to physically interact with their surrounding. In direct consequence the learning, planning, and execution of safe and legible interactions has become a widely taken research direction. Clearly, the rise of a new generation of commercial robots capable of physical interaction has also contributed to the large interest in the field. The robotics research and industrial community expects these systems to open up new markets and to push robotics further toward domestic applications that may also involve even more complex and possibly mobile manipulators.

However, despite this recent success in research and also in the commercialization of assistance robots, there are many open research questions that need to be tackled before this class of systems can become a commodity not only in early adopter industrial applications but also on a broader scale: Continuing the road toward safe robotics by tightly coupling injury biomechanics and safe interaction control with lightweight and compliant robot design will further push the boundaries and build the foundation of pHRI. On the other hand, learning interaction controllers and planning intuitive and safe interactions are still very young fields, however, they are the key to solving the long-term physical interaction problem. Furthermore, the current application of assistance robots in real-world problems will bring further novel research questions. The recent

use of these robots clearly underlines that the programming models and paradigms of interaction and soft manipulation are very different from classical industrial robot programming. In particular, they go be-

yond simple pick and place models toward models of *force based programming*, an interesting research question currently being investigated by various researchers worldwide.
